Using data recorded with the Belle detector, we observe a new excited hyperon, an \( \Omega^- \) candidate decaying into \( \Xi^0 K^- \) and \( \Xi^- K^0 \) with a mass of \( 2002.4 \pm 0.7 \text{(stat)} \pm 0.6 \text{(syst)} \) MeV/c\(^2\) and a width of \( \Gamma = 64.3^{+22.5}_{-11.7} \text{(stat)} \pm 1.6 \text{(syst)} \) MeV. The \( \Omega^- \) is seen primarily in \( \Upsilon(1S), \Upsilon(2S), \) and \( \Upsilon(3S) \) decays.

DOI: 10.1103/PhysRevLett.121.052003

We search for excited \( \Omega^- \) decays into \( \Xi^0 K^- \) and \( \Xi^- K^0 \) [15], with subsequent decays into \( \Xi^- \rightarrow \Lambda \pi^- , \Xi^0 \rightarrow \Lambda \pi^0, K^0 \rightarrow \pi^+ \pi^- , \Lambda \rightarrow p \pi^- , \) and \( \pi^0 \rightarrow \gamma \gamma \). An excited \( \Omega^- \) would be expected to decay strongly, and, because of isospin symmetry, with almost equal branching fractions, into the above two decay modes, and they would likely dominate the decays of any \( \Omega^- \) with a mass between the \( \Xi K \) and \( \Xi(1530)K \) thresholds.

The Belle detector was a large solid-angle spectrometer comprising six subdetectors: the silicon vertex detector (SVD), the 50-layer central drift chamber (CDC), the aerogel Cherenkov counter (ACC), the time-of-flight scintillation counter (TOF), the electromagnetic calorimeter (ECL), divided into the barrel ECL in the central region and the forward and backward end caps at smaller angles with respect to the beam axis, and the \( K_L^0 \) and muon detector. A superconducting solenoid produces a 1.5 T magnetic field throughout the first five of these subdetectors. The detector is described in more detail in Ref. [10]. Two inner detector configurations were used. The first comprised a 2.0 cm radius beam pipe and a 3-layer SVD and the second a 1.5 cm radius beam pipe and a 4-layer SVD and a small-cell inner CDC.

Charged particles \( \pi^+, K^- \), and \( p \) are selected using the information from the tracking (SVD, CDC) and charged-hadron identification (CDC, ACC, TOF) systems combined into a likelihood \( L(h_1; h_2) = L_{h_1}/(L_{h_1} + L_{h_2}) \), where \( h_1 \) and \( h_2 \) are \( p, K, \) and \( \pi \) as appropriate. Kaon candidates are defined as those with \( L(K; \pi) > 0.9 \) and \( L(K; p) > 0.9 \), which is approximately 83% efficient. For protons, the requirements are \( L(p; \pi) > 0.2 \) and \( L(p; K) > 0.2 \), while for charged pions \( L(\pi; p) > 0.2 \) and \( L(\pi; K) > 0.2 \); these requirements are approximately 99% efficient.

The \( p \) candidates are reconstructed from two neutral clusters detected in the ECL, each consistent with being due to a photon and having an energy greater than 30 MeV in the laboratory frame (for those in the end cap calorimeter, the energy threshold is increased to 50 MeV).

Candidate \( \Lambda(K_S^0) \) decays are made from \( p \pi^- (\pi^+ \pi^-) \) pairs with a production vertex significantly separated from

the average interaction point (IP) and a reconstructed invariant mass within 3.5 (5.0) MeV/$c^2$ of the peak values.

Each $\Xi^-$ candidate is reconstructed by combining a $\Lambda$ candidate with a $\pi^-$ candidate. The vertex formed from these two is required to be at least 0.35 cm from the IP, to be a shorter distance from the IP than the $\Lambda$ decay vertex, and to signify a positive $\Xi^-$ flight distance. The $\Xi^0 \rightarrow \Lambda\pi^0$ reconstruction is complicated by the fact that the $\pi^0$ has negligible vertex position information. Combinations of $\Lambda$ and $\pi^0$ candidates are made, and then, assuming the IP to be the production point of the $\Xi^0$, the sum of the $\Lambda$ and $\pi^0$ momenta is taken as the momentum vector of the $\Xi^0$ candidate. The intersection of this trajectory with the reconstructed $\Lambda$ trajectory is then found, and this position is taken as the decay location of the $\Xi^0$ hyperon. The $\pi^0$ is then remade from the two photons using this location as its point of origin. The reconstructed invariant mass of the $\pi^0$ candidate must be within 10.8 MeV$/c^2$ of the nominal mass (approximately 94% efficient). To reduce the large combinatorial background, the momentum of the $\pi^0$ candidate is required to be greater than 200 MeV/$c$. Combinations are retained if they have a decay location of the $\Xi^0$ indicating a positive $\Xi^0$ path length of greater than 2 cm but less than the distance between the $\Lambda$ decay vertex and the IP. The refitting of the $\pi^0$ at the reconstructed $\Xi^0$ decay vertex improves the $\Xi^0$ mass resolution by around 15%.

The resultant invariant mass plots for the $\Xi^0$ and $\Xi^-$ candidates are shown in Fig. 1. The red vertical arrows indicate the limits of the reconstructed invariant masses of the candidates retained for further analysis, which are $\pm$5.0 and $\pm$3.5 MeV/$c^2$ around the central values of the $\Xi^0$ and $\Xi^-$ mass peaks, respectively, which are each approximately 95% efficient. For the $\Xi^0$, the value of the mass peak is $1.3155$ GeV$/c^2$ and is higher than the PDG [1] value of $1.31486 \pm 0.00020$ GeV/$c^2$. This difference is later used in the estimate of the systematic uncertainty of the $\Omega^-$ resonance mass measurement.

The $\Xi^0$ and $\Xi^-$ candidates are kinematically constrained to their nominal masses [1] and then combined with $K^-$ and $K^0_S$ candidates, respectively. The two particle combinations are kinematically constrained to come from a common vertex at the IP, and the $\chi^2$ of this is required to be consistent with the daughters being produced by a common parent. For the $\Xi^0K^-$ case, if there is more than one candidate with the same $\Lambda$ and $K^-$ but a different $\pi^0$, the one with the higher $\pi^0$ momentum is kept and others discarded to avoid double counting. This occurs around 3% of the time.

Figure 2 shows the $\Xi^0K^-$ and $\Xi^-K^0_S$ invariant mass distributions in data taken at the $\Upsilon (1S)$, $\Upsilon (2S)$, and $\Upsilon (3S)$ resonance energies. Excesses are present in both distributions at around 2.01 GeV/$c^2$. It should be noted that real $\Xi^0K^-$ combinations have three units of strangeness and are therefore highly suppressed. In contrast, $\Xi^-K^0_S$ combinations may have one unit of strangeness and thus have a larger combinatorial background.

A simultaneous fit applied to the two distributions is shown in Fig. 2 and uses fitting functions where the signal functions are Voigtian functions (Breit-Wigners convolved with a Gaussian resolution functions) and the background functions second-order Chebyshev polynomials. The masses and intrinsic widths of the two Voigtian functions are kept the same. The resolution functions are obtained from Monte Carlo (MC) events, generated using EVTGEN [16] with the Belle detector response simulated using the GEANT3 [17] framework, and parametrized as Gaussian distributions with widths of 2.27 MeV/$c^2$ for $\Xi^0K^-$ and 1.77 MeV/$c^2$ for $\Xi^-K^0_S$. The fit is made to the binned invariant mass distributions with a large number of small bins, using the maximum-likelihood method. A convenient test of the goodness-of-fit is the $\chi^2$ per degree of freedom ($\chi^2$/d.o.f.) for the distribution plotted in 2.5 MeV/$c^2$ bins. The signal yields, mass, intrinsic width, and $\chi^2$/d.o.f. resulting from this fit are listed in Table I. We calculate the statistical significance of the signal by excluding the peaks from the fit, finding the change in the log-likelihood ($\Delta \ln(L)$) and converting this to a $p$-value taking into account the change in d.o.f. This is then converted to an

![Image of reconstructed invariant mass distributions](PHYSICAL REVIEW LETTERS 121, 052003 (2018))

FIG. 1. Reconstructed invariant mass distributions, using all Belle data, of (a) $\Lambda\Xi^0$ and (b) $\Lambda\Xi^-$ combinations after all requirements. The arrows show the mass windows used for $\Xi^0$ and $\Xi^-$ identification.
The statistical significances are listed in Table I. The distributions show excesses in the signal region, and their masses are in the range of 946 MeV. For the remainder of the Belle data, which comprises a total of 2012 GeV/c², the significance values are computed using the effective number of standard deviations \( n_σ \). For this simultaneous fit, we find \( n_σ = 8.3 \).

Table I lists the results of fits obtained from fitting each of the two distributions separately. The signals in the \( \Xi^0 K^- \) and \( \Xi^- K^0_S \) mass distributions have significances of \( n_σ = 6.9 \) and \( n_σ = 4.4 \), respectively, and have statistically compatible masses and widths.

We have performed a series of checks to confirm the stability of the signal peak. Reasonable changes to the selection criteria of the daughter particles produce changes in the signal yield consistent with statistics. It would be surprising if an \( \Omega^- \) were not also produced in continuum \( e^+ e^- \to q\bar{q} \) events. In Fig. 3, we present mass distributions as in Fig. 2 but for the remaining of the Belle data, which comprise a total of 946 fb⁻¹ taken mostly at the \( \Upsilon(4S) \) energy but also in the continuum below and above this energy as well as at the \( \Upsilon(5S) \). For the fits shown in Fig. 3, we use second-order Chebyshev background functions together with signal functions with mass and width fixed to the values found in the \( \Upsilon(1S, 2S, 3S) \) data. Both distributions show excesses in the signal region, and their statistical significances are listed in Table I.

Taking into account the detection efficiency of the two modes, we use the results of the simultaneous fit to the \( \Upsilon(1S, 2S, 3S) \) data to calculate the branching fraction ratio \( R = \frac{B(\Omega^- \to \Xi^0 K^-) / B(\Omega^- \to \Xi^- K^0)}{1.2 \pm 0.3} \), where statistical uncertainties dominate. With perfect isospin symmetry, this ratio would be 1, but the isospin mass splitting of the \( \Xi \) and \( K \) doublets will lead to an increase of up to approximately 15% depending on the spin associated with decay. The obtained value of \( R \) is consistent with the expectation.

The significance of the observation is largely unaffected by systematic uncertainties associated with the limited knowledge of the resolution and momentum scale of the detector. However, the use of different background functions can change the significance values. If we replace the background functions by third-order Chebyshev polynomials, the significance of the signal in the simultaneous fit is reduced to \( n_σ = 7.2 \). We take this value as the signal significance including systematic uncertainties. We also investigated the possibility of a further signal at around a mass of 1.95 GeV/c² where the data show an excess of events. This excess is not statistically significant, and its inclusion in the fit makes a negligible change to the significance of the signal at 2.012 GeV/c².

The dominant systematic uncertainty of the mass measurement is due to the masses of the \( \Xi^0 \) and \( \Xi^- \) hyperons, which enter almost directly into the calculation of the \( \Omega^- \) mass. Conservatively, we take the difference between the reconstructed \( \Xi^0 \) mass and the PDG value 0.6 MeV/c². The Belle charged-particle momentum scale is very well understood, and the uncertainty in the \( \Omega^- \) mass measurement due to this is much smaller than 0.6 MeV/c². Similarly, changing the fit function to a relativistic Breit-Wigner has negligible effect on the mass value.

MC simulation is known to reproduce the resolution of mass peaks within 10% over a large number of different systems. The resultant systematic uncertainty in \( \Gamma \) from this source is ±0.37 MeV. Changing the background shapes to third-order Chebyshev polynomials changes the measured value of \( \Gamma \) by 1.6 MeV, and this is the dominant contributor to the systematic uncertainty of the width.

The theoretical models [2–7] predict a \( J^P = \frac{1}{2}^- \) and \( J^P = \frac{3}{2}^- \) pair of excited \( \Omega^- \) states in this mass region but with large differences in their mass predictions. Our value

is, in general, closer to the those for the $J^P = \frac{3}{2}^-$ state. We also note that an $\Omega^{-}\pi^-$ with $J^P = \frac{3}{2}^-$ is restricted to decay to $\Xi K$ via a $d$ wave, whereas a state with $J^P = \frac{3}{2}^-$ could decay via an $s$ wave. Thus, the rather narrow width observed implies that the $\frac{3}{2}^-_2$ identification is more likely.

In summary, we have reported the observation of a new resonance, which we identify as an excited $\Omega^{-}\pi^-$ baryon, found in the decay modes $\Omega^{-}\pi^- \rightarrow \Xi^0 K^-$ and $\Omega^- \rightarrow \Xi^- K^0$. The measured mass of the resonance is $[20.12 \pm 0.7 \text{ (stat)} \pm 0.6 \text{ (syst)}] \text{ MeV}/c^2$, and its width $\Gamma [6.4^{+2.5}_{-2.0} \text{ (stat)} \pm 1.6 \text{ (syst)} \text{ MeV}]$. This new resonance has a mass $340 \text{ MeV}/c^2$ higher than the ground state, and thus helps fill the large gap in the $\Omega^{-}$ spectrum between the ground state and the already observed excited states. It is found primarily in the decay of the narrow resonances $\Upsilon(1S)$, $\Upsilon(2S)$, and $\Upsilon(3S)$.
