Running head

Stomatal model with non-stomatal limitation

Abstract

Vapour pressure deficit (D) is projected to increase in the future as temperatures rise. In response to increased D , stomatal conductance (g_s) and photosynthesis (A) are reduced, which may result in significant reductions in terrestrial carbon, water, and energy fluxes. It is thus important for gas exchange models to capture the observed responses of g_s and A with increasing D .

We tested a series of coupled A - g_s models against leaf gas exchange measurements from the Cumberland Plain Woodland (Australia), where D regularly exceeds 2 kPa and can reach 8 kPa in summer. Two commonly used A - g_s models (Leuning 1995 and Medlyn et al. 2011) were not able to capture the observed decrease in A and g_s with increasing D at the leaf scale. To explain this decrease in A and g_s , two alternative hypotheses were tested: hydraulic limitation (i.e., plants reduce g_s and/or A due to insufficient water supply) and non-stomatal limitation (i.e., downregulation of photosynthetic capacity). We found that the model that incorporated a non-stomatal limitation captured the observations with high fidelity and required the fewest number of parameters. While the model incorporating hydraulic limitation captured the observed A and g_s , it did so via a physical mechanism that is incorrect.

We then incorporated a non-stomatal limitation into the stand model, MAESPA, to examine its impact on canopy transpiration and gross primary production. Accounting for a non-stomatal limitation reduced the predicted transpiration by ~19%, improving the correspondence with sap flow measurements, and gross primary production by ~14%. Given the projected global increases in D associated with future warming, these findings suggest that models may need to incorporate non-stomatal limitation to accurately simulate A and g_s in the future with high D . Further data on non-stomatal limitation at high D should be a priority, in order to determine the generality of our results and develop a widely applicable model.

Keywords: Vapour pressure deficit, stomatal conductance, non-stomatal limitation, hydraulic limitation, model-data assimilation, photosynthesis

Introduction

Vapour pressure deficit (D) is the difference between the amount of water vapour that the air can hold at saturation (e_s) and the actual amount of water vapour in the air (e_a ; Monteith and Unsworth, 2013). With rising air temperatures, e_s increases exponentially and as a result, D is projected to increase strongly into the future (Ficklin and Novick, 2017). At the leaf level, as D increases and plant water supply becomes limiting, a direct reduction in stomatal conductance (g_s) occurs to limit transpiration, which inevitably also affects photosynthesis (A ; Cowan and Farquhar, 1977). The reduction of A and potentially transpiration due to increasing D has important implications for global carbon-climate predictions (Reichstein et al., 2013; Will et al., 2013). Thus, it is crucial to understand the response of vegetation to the projected increase in D (Novick et al., 2016).

The challenges involved in modelling g_s responses to high D have been discussed since the late 1970's (Cowan, 1978; Farquhar, 1978). Monteith (1995) characterised the response of g_s to D as consisting of two different regimes: (i) regime A—where g_s gradually declines with D , but transpiration (E) increases with D ; (ii) regime B—where g_s declines non-linearly with D , resulting in a peak and then decline in E . Regime A is the most commonly observed pattern and occurs at intermediate D (0.5-2 kPa). It also represents the range of leaf level measurements most commonly used to parameterise models of g_s (e.g., Ball et al., 1987; Leuning, 1995; Medlyn et al., 2011). Regime B takes place at higher D ($D > 2$ kPa), which is typically rare in humid ecosystems but common in hot and dry ones (e.g., Franks et al., 1997; Thomas and Eamus, 1999; MacFarlane et al., 2004; Whitley et al., 2013; Gimeno et al., 2018; Renchon et al., 2018).

Current representations of g_s in terrestrial biosphere models (TBMs) differ in their sensitivity to D , especially at $D > 2$ kPa (i.e., regime B; De Kauwe et al., 2015; Knauer et al., 2015; Franks et al., 2017), which has carry-over effects on TBM predictions at high D . The g_s model of Leuning (1995) has a strong D dependence (g_s depends on the reciprocal of D), which yields a reduction in E at high D . However, it can be difficult to parameterise the Leuning model such that it can fit data at both high and low D (Duursma et al., 2014). The parameter values most commonly used are biased towards low D (e.g., those used in the Community Atmosphere Biosphere Land Exchange (CABLE) land surface model (Kowalczyk et al., 2015) or the Sheffield Dynamics Global Vegetation Model (Woodward et al., 1995)). Alternatively, Medlyn et al. (2011) proposed an optimality model, in which g_s

depends on $D^{-0.5}$. Due to this lower sensitivity of g_s to D compared to the Leuning model, the Medlyn model does not predict a reduction in E at high D (i.e., regime B).

The reduction of E at high D in regime B could result from a hydraulic limitation (Buckley, 2005). Experimental observations show that g_s is strongly linked to guard cell and epidermal turgor (e.g., Franks et al., 1997; Franks, 2004) and not simply to environmental conditions (i.e., D). Tuzet et al. (2003) proposed a model coupling g_s to leaf water potential (ψ_L). The ψ_L term in the Tuzet model is determined by the balance of plant water use via stomata and the water supply, which is calculated as the product of hydraulic conductance and the difference between leaf and soil water potentials. In the Tuzet model, ψ_L is solved iteratively by balancing the demand and supply. If the hydraulic conductance is held constant, the Tuzet model will not yield a decline in transpiration at high D because a reduction in ψ_L cannot occur at the same time as a reduction in transpiration (Farquhar 1978). However, reductions in hydraulic conductance can occur within the xylem by cavitation (Tyree and Sperry, 1989) or in the outside xylem component of the pathway via a variety of mechanisms (Scoffoni et al., 2017). A very negative ψ_L leads to a large pressure difference but low conductance, the net effect of which can lead to a reduction in water supply and thus a decrease in g_s . Although theoretically plausible, the hydraulic limitation hypothesis has not been extensively tested against observations.

An alternative hypothesis to explain the coupled A - g_s response at high D is a non-stomatal limitation of A (Dewar et al. 2018; Gimeno et al. 2019). The mechanism for such a non-stomatal limitation is not clear, but it could potentially involve biochemical regulation or a reduction in mesophyll conductance. For example, Duursma et al. (2014) proposed that the reduction of E at high D is driven by a decrease in apparent carboxylation capacity (V_{cmax}) at the high temperatures ($>30^\circ\text{C}$) that accompany high D . This hypothesis was supported by leaf and canopy scale measurements in a whole tree chamber experiment (Duursma et al., 2014). Low leaf water potential at high D could also reduce apparent photosynthetic capacity via a downregulation of the capacity of photosynthetic biochemistry or a reduction in mesophyll conductance (Tezara et al., 1999; Lawlor and Cornic, 2002; Lawlor and Tezara, 2009), which would subsequently drive a coupled reduction in g_s . Such an effect is increasingly reported in soil drought studies (e.g., Zhou et al., 2013, 2014; Verhoef and Egea, 2014; Drake et al., 2017). Incorporating a non-stomatal limitation into TBMs has led to improved predictions of soil drought responses (Keenan et al., 2010, Verhoef and Egea, 2014; De Kauwe et al., 2015; Drake et al., 2017). Although these studies have shown the importance of non-stomatal

limitation under soil drought (i.e., via reduced photosynthetic capacity), it is unclear whether high D can cause the same non-stomatal limitation.

Here, we evaluate alternative stomatal modelling approaches at a woodland site where D reaches high levels every summer (mean daily maximum = 2.7 kPa; maximum = 8 kPa). We first test leaf-scale models against *in situ* observations which showed a reduction in g_s and A with increasing D (Gimeno et al., 2016). We then implement the best model into a canopy scale model against whole-tree-scale sap flow data that showed a decrease in transpiration at high D (Gimeno et al., 2018). We aim to quantify how well the alternative gas exchange models captured the high D responses of both g_s and A .

Methods

We tested five leaf-scale g_s models in this study (Table 1): (i) the Medlyn model (Medlyn et al., 2011), which is derived from optimal stomatal theory and assumes that g_s depends on the reciprocal of $D^{0.5}$; (ii) the Leuning model (Leuning, 1995), which has a similar functional form to the Medlyn model but assumes a stronger g_s sensitivity to D ; (iii) the Tuzet stomatal model (Tuzet et al., 2003), which assumes a g_s sensitivity to ψ_L , incorporating a reduction of hydraulic conductance with low ψ_L (hereafter referred as Tuzet K-PSI); (iv) the Tuzet stomatal model incorporating a non-stomatal limitation at low ψ_L (hereafter referred as Tuzet V-PSI); and (v) the Medlyn model, incorporating a non-stomatal limitation that increases with increasing D (hereafter referred as Medlyn V-D). The comparison between the performance of Medlyn and Leuning model tests whether increasing the sensitivity of g_s to D improves model performance. The Tuzet K-PSI model was chosen to test whether considering a hydraulic limitation improved model performance. The comparison between the Tuzet V-PSI and Medlyn V-D models was designed to test whether this assumption was necessary to improve predictions at high D and to explore the best way to represent non-stomatal limitation.

Sites

Data were obtained from two sites in the Cumberland Plain Woodland. The first site is the *Eucalyptus* Free-air-CO₂-Enrichment site (EucFACE) in Richmond, Western Sydney, Australia (33.62°S, 150.73°E). The site is a natural mature woodland, dominated by *Eucalyptus tereticornis*. EucFACE consists of six circular plots (referred to as “rings”

hereafter), each of which has a diameter of 25 m (Gimeno et al., 2016). The rings receive two CO₂ concentrations: ambient (rings 1, 4, 5; ambient CO₂ ≈ 400 μmol mol⁻¹) and elevated (rings 2, 3, 6; ambient CO₂+150 μmol mol⁻¹). The data from the elevated CO₂ rings were included in this study to increase the number of observations for statistical testing, but responses to elevated CO₂ are not a focus of the study (see Gimeno et al., 2016, 2018 for analysis of effects of elevated CO₂). Meteorological data measured at EucFACE during the measurement period of the year 2013 are shown in Figure S1. The second site is 10 km south of EucFACE in the Castlereagh Nature Reserve, Sydney, Australia (33.39°S, 150.46°E) (Zeppel et al., 2008). This site is also a mature natural woodland with *E. parramattensis* as the dominant species, a local species closely related to *E. tereticornis*.

Measurements

This study used three types of data: leaf gas exchange (Zeppel et al., 2008; Gimeno et al., 2016), xylem vulnerability curves, and sap flow (Zeppel et al., 2008; Gimeno et al., 2018). Leaf gas exchange and xylem cavitation data were used in parameterization as well as evaluation of the g_s models. Sap flow data were used in whole-tree scale evaluations to test transpiration predictions of the canopy scale model.

Diurnal leaf gas exchange measurements were made throughout the day under prevailing field conditions using LiCOR 6400XT at EucFACE in 2013 (Gimeno et al., 2016) and a LCpro+ system (ADC BioScientific, Hoddesdon, UK) at Castlereagh in 2006 (Zeppel et al., 2008). Canopy access at EucFACE was provided by a crane (canopy height = 20m) whereas canopy access at Castlereagh was provided by a portable rising work platform (canopy height = 2-8 m), both suitable to reach the upper canopy. The EucFACE data were measured at saturating photosynthetically active radiation (1800 μmol m⁻² s⁻¹). The Castlereagh data were measured at ambient light levels, so we only used data with saturating light (>1200 μmol m⁻² s⁻¹). At EucFACE, leaf water potential measurements at pre-dawn, morning (9:30-11:30), and afternoon (13:00-15:00) were also made by Gimeno et al. (2016).

In addition to the four diurnal gas exchange campaigns at EucFACE, repeated light- and temperature-controlled photosynthesis-CO₂ response ($A-C_i$) curves on the same 3 or 4 trees in each ring were measured and used to calculate the maximum apparent electron transport rate (J_{max} ; μmol m⁻² s⁻¹) and apparent carboxylation capacity (V_{cmax} ; μmol m⁻² s⁻¹). The J_{max} and V_{cmax} values were estimated with the “fitacis” function from the *plantecophys* R package

(Duursma, 2015). The temperature dependencies of J_{max} and V_{cmax} were obtained from a different set of $A-C_i$ curves measured at four leaf temperatures ranging between 20 and 40 °C during February 2016. We fitted peaked Arrhenius functions to the values of J_{max} and V_{cmax} obtained at each measurement temperature (Medlyn et al., 2002). The resulting J_{max} and V_{cmax} at 25°C (i.e., $J_{max.25}$ and $V_{cmax.25}$) values were averaged for each ring on each measurement date. We also estimated one-point V_{cmax} from the diurnal measurements using the “one-point method” (De Kauwe et al. 2016). As a result, each diurnal gas exchange measurement corresponded to a modelled V_{cmax} based on $A-C_i$ curve data and the temperature response, and an *in situ* V_{cmax} based on the “one-point method”.

A hydraulic vulnerability curve for *E. tereticornis* was constructed using benchtop dehydration (Sperry et al. 1988). Two-metre-long branches were excised from six mature canopy trees located outside the rings at EucFACE, using the canopy crane. Collections were made in the early morning (between first light and sunrise). Branches were placed in large plastic bags with moist towels to prevent dehydration and cut ends were recut under water and allowed to rehydrate. Branches were transported in water and were stored in a cool room 24 hours before measurements. Stem percent loss of conductivity was measured using hydraulic flow measurements on increasingly dehydrated branch segments using a flowmeter (Liqui-Flow L10, Bronkhorst High-Tech BV, Ruurlo, Gelderland, Netherlands) at low pressure (< 4 kPa). Four to six stem segments were measured per large branch at progressively lower water potentials (measured on covered leaves using a pressure chamber – PMS Instrument Company, Albany, OR, USA). To quantify the impact of cavitation for the Tuzet models, a Weibull function following Ogle et al. (2009) was fitted to produce a vulnerability curve using the ‘fitplc’ function in the *fitplc* R package (Duursma and Choat, 2017).

Canopy transpiration was estimated with sap flow measurements at both the EucFACE and the Castlereagh sites. At EucFACE, two custom-built two-probe heat-pulse sensors (Edwards Industries, Havelock North, New Zealand) were installed at two positions on each tree, on three or four trees per ring (Gimeno et al. 2018). The data from all six rings were upscaled to estimate stand averages using sap wood area, which was allometrically calculated with measured stem diameter. The volumetric soil water content (θ) of the site was measured every ~20 days using neutron measurements at 25 cm intervals (NMM, 503DR Hydroprobe®, Instroteck, NC, USA) and averaged to the mean moisture of the top 150 cm of the soil (Figure 1; Gimeno et al. 2018). Sap flow at the Castlereagh site was obtained from

Zeppel et al. (2008). The measurements used two-probe heat pulse sensors and sampled six trees with two sensors per tree from June to December 2006. The corresponding soil moisture measurements at Castlereagh were recorded with an array of frequency domain reflectometry sensors (Theta Probe, ML2-X; Delta-T devices, Cambridge,UK) for the top 70 cm.

Leaf gas exchange models

We used the Medlyn model as our baseline stomatal conductance model because it requires the fewest parameters (Medlyn et al., 2011):

$$g_s = 1.6 \cdot \left(1 + \frac{g_{1.MED}}{\sqrt{D}}\right) \cdot \frac{A}{c_a} \quad (1)$$

where g_s is the stomatal conductance to water vapour ($\text{mol m}^{-2} \text{s}^{-1}$); $g_{1.MED}$ is the optimal stomatal behaviour parameter ($\text{kPa}^{0.5}$; see detailed explanation in Medlyn et al., (2011)); A is the CO_2 assimilation rate ($\mu\text{mol m}^{-2} \text{s}^{-1}$); c_a is the atmospheric CO_2 concentration ($\mu\text{mol mol}^{-1}$). We modelled A with the *plantecophys* R Package (Duursma, 2015), which uses the Farquhar-von Caemmerer-Berry photosynthesis model (Farquhar et al., 1980).

An earlier g_s model was proposed by Leuning (1995), who assumed an inverse stomatal response to D :

$$g_s = 1.6 \cdot g_{1.LEU} \cdot \frac{A}{c_a} \cdot \frac{1}{1+D/D_0} \quad (2)$$

where $g_{1.LEU}$ is an empirical slope determining the sensitivity of g_s to A and other environment variables (dimensionless); and D_0 reflects the sensitivity of g_s to D (kPa). Both the Medlyn and Leuning models can include a minimum stomatal conductance, g_0 , as an intercept (Duursma et al., 2019). This study assumed $g_0 = 0$ since the estimated g_0 is negligible (Gimeno et al., 2016).

We also tested a modified version of the model proposed by Tuzet et al. (2003), following Duursma and Medlyn (2012):

$$g_s = 1.6 \cdot g_{1.TUZ} \cdot \frac{A}{c_a} \cdot f_s(\psi_L) \quad (3)$$

where $g_{1.TUZ}$ is an empirical slope parameter and f_s is the sigmoidal function defined as:

$$f_s(\psi_L) = \frac{1+\exp(s_f \cdot \psi_f)}{1+\exp(s_f \cdot (\psi_f - \psi_L))} \quad (4)$$

where ψ_L is leaf water potential (MPa); ψ_f is an empirical reference water potential (MPa), and s_f is a sensitivity parameter describing the steepness of the response of g_s to ψ_f (MPa⁻¹). The Tuzet model resembles the Medlyn and Leuning models but replaces the dependence on D with a function of ψ_L .

The leaf water potential ψ_L is obtained as follows. Assuming that the transpiration is a balance of demand and supply:

$$E = K \cdot (\psi_s - \psi_L) = g_s \cdot D / P_{atm} \quad (5)$$

where K is the soil-to-leaf hydraulic conductance (mol m⁻² s⁻¹ MPa⁻¹); ψ_s is the soil water potential (MPa) and P_{atm} is the atmospheric air pressure (kPa). To solve for ψ_L requires a value for K , which is assumed to decrease as plant water potential becomes more negative (Tyree and Sperry 1989):

$$K = K_{max} \cdot R_{PLC} \quad (6)$$

where K_{max} is the maximum hydraulic conductance (mol m⁻² s⁻¹ MPa⁻¹). R_{PLC} is the percentage loss of hydraulic conductance and takes the form of a Weibull function as fitted by Neufeld et al. (1992):

$$R_{PLC} = \frac{1}{1 + \exp(a \cdot (\psi_L - \psi_{50}))} \quad (7)$$

where a and ψ_{50} are fitted parameters, representing the rate of decline of the curve and the leaf water potential at which plant hydraulic conductance is reduced to 50% respectively. This equation was fitted to the hydraulic vulnerability curves described above. Combining Equations 3 – 7 allows both ψ_L and g_s to be predicted.

We tested two alternative ways to represent non-stomatal limitations. In the first, V_{cmax} was assumed to decline with leaf water potential (the V -PSI hypothesis):

$$V = V_{cmax} \frac{1 + \exp(s_{fv} \cdot \psi_{fv})}{1 + \exp(s_{fv} \cdot (\psi_{fv} - \psi_L))} \quad (8)$$

where V is the V_{cmax} modified by non-stomatal limitation and s_{fv} and ψ_{fv} are fitted parameters. ψ_{fv} is an empirical reference water potential (MPa), and s_{fv} is a sensitivity parameter describing the “steepness” of the response of V_{cmax} to ψ_{fv} (MPa⁻¹). Note that this is the same form of sigmoidal function as used in the Tuzet model (Eqn. 3).

In the second representation of the non-stomatal limitation, we derived a direct empirical relationship between V_{cmax} and D (the V - D hypothesis):

$$V = \min(10, V_{cmax} \cdot (1 - c_D \cdot D)) \quad (9)$$

where c_D is a fitted parameter (kPa^{-1}). This relationship is different from that in Eqn. 8 because it assumes the apparent carboxylation capacity directly responds to D . Although the mechanism for such a change is unclear, this simple empirical approach allows us to explore the possibility of direct downregulation of apparent V_{cmax} and J_{max} . Similar simple empirical approaches have been used to explore non-stomatal limitation under low soil moisture content (e.g., Keenan et al., 2010, Verhoef and Egea, 2014; De Kauwe et al., 2015; Drake et al., 2017). We set a minimum V_{cmax} of 10 ($\mu\text{mol m}^{-2} \text{s}^{-1}$) to avoid negative values produced by the linear decline of V_{cmax} with D . The same relationship is assumed for J_{max} .

We assumed that the impact of reduced soil water availability could be represented in the Tuzet model by the reduction of soil moisture potential (ψ_s), which was estimated from the pre-dawn leaf water potential (ψ_{pd} ; MPa). For the Medlyn and Leuning models, we assumed an exponential dependence of the g_l parameter on ψ_{pd} following Zhou et al. (2013):

$$g_l = g_{l.MAX} \cdot \exp(\beta \cdot \psi_{pd}) \quad (10)$$

where g_l represents $g_{l.MED}$ and $g_{l.LEU}$; $g_{l.MAX}$ is g_l when $\psi_{pd} = 0$; β represents the sensitivity of g_l to ψ_{pd} . The impact of dry soil was implemented to account for the variation in the soil water availability among the campaigns.

Parameterisation of leaf gas exchange models

We used R (version 3.4.1 R Core Team) as the modelling and statistical tool. We used measured values of incident photosynthetically active radiation, leaf temperature, atmospheric CO_2 concentration, D , ψ_{pd} , J_{max} , and V_{cmax} for the diurnal gas exchange data (at EucFACE only). We then parameterized the Medlyn and Leuning models at leaf scale using the differential evolution algorithm (*DEoptim* package) to fit all the parameters ($g_{l.MAX}$, β , D_0 , and c_D) in the coupled A - g_s model against the measured A and g_s data. We used a similar approach to determine the unknown parameter values in the Tuzet models. As a result, all the models tested at the leaf-scale were fitted to measurements of A and g_s .

The fidelity of the leaf-scale models was evaluated via: (i) the Bayesian Information Criteria (BIC), which considered the relative residuals of predictions (both A and g_s) as well as the number of parameters in the models; (ii) the coefficient of determination (R^2) of both A and

g_s . We ranked the models with these measures and selected the one with the highest overall ranking.

Stand scale model

We implemented the Medlyn model (Eqn. 1) with V - D relationship (Eqn. 9) into a process-based stand-scale model MAESPA (Duursma and Medlyn 2012). For the purposes of this study, the plant hydraulics sub-model of MAESPA was not used; instead soil water content was prescribed rather than being simulated. The stand simulation included all six rings in EucFACE and covered the period between 1 January 2013 to 31 December 2013 on a half hourly basis. MAESPA considers the radiative transfer to an array of grid points within each tree crown and calculates gas exchange at each grid point based on light interception at each timestep. Understory plants were not included here because they do not contribute to tree transpiration. The model was parameterised with data on size and position of each tree as well as the smoothed and gap-filled leaf area index (Duursma et al., 2016; Figure S1).

Meteorological (Figure S1) and soil water content data (Figure 1) observed in each ring were input to the model. The original met data were aggregated to half-hourly averages and gap-filled with nearest available values (less than 1% of the total). Canopy physiology was parameterized with measurements of the light response of photosynthesis, dark respiration rate, and the temperature response of photosynthesis and respiration, all made at EucFACE and assumed not to vary across treatments. We assumed a minimum g_s (Duursma et al., 2019) of $0.01 \text{ (mol H}_2\text{O m}^{-2} \text{ leaf s}^{-1}\text{)}$ during daytime to avoid zero transpiration at extreme environmental conditions (e.g., high D). The transpiration of the canopy in the model is given by the Penman-Monteith equation, which considers net radiation, windspeed, relative humidity, and g_s .

The impact of low soil water content on stomatal conductance in MAESPA was modelled as a function of g_l and volumetric soil water (θ) content following Drake et al. (2017):

$$g_l = g_{l.SAT} \cdot \left(\frac{\theta - \theta_{min}}{\theta_{max} - \theta_{min}} \right)^q \quad (11)$$

where $g_{l.SAT}$ is the value of g_l ($\text{kPa}^{0.5}$) at saturating soil water content; θ_{max} and θ_{min} are empirically fitted parameters defining the upper and lower boundaries beyond which g_l is not affected by θ ; and q is the parameter describing the non-linearity of the function. We fitted Eqn. 11 to the data from Gimeno et al. (2016) to obtain the values of θ_{max} , θ_{min} , and q (0.25,

0.11, and 0.38 respectively) with the non-linear least squares method (nls, R function). The fitted relationship between $g_{l.MAX}$ and θ used in the model is shown in Figure S2. J_{max} in MAESPA is taken as a constant mean of 159 ($\mu\text{mol m}^{-2} \text{s}^{-1}$) for all rings and time. V_{cmax} in MAESPA also remained constant over time but taken as 83 ($\mu\text{mol m}^{-2} \text{s}^{-1}$) for elevated CO_2 rings and 91 for ambient CO_2 rings as per measurements (Ellsworth et al., 2017; Wujeska-Klaue et al., 2019). The parameter values used in MAESPA are presented in Table S2.

Results

Leaf gas exchange models

The leaf gas exchange data from EucFACE showed a clear decline in both A and g_s with increasing D (Figure 2). The baseline model (Medlyn with constant V) was unable to capture the response of A (Figure 3a) or g_s (Figure 3b) to D . As a result, this model ranked lowest amongst the models tested (BIC = -2452; Table 1). It over-predicted A at high D but under-predicted g_s at low D . The Leuning model, despite its stronger sensitivity to D , shared the same problems as the Medlyn model (Table 1; Figure 3 c and d). In addition, we obtained unrealistic parameter values ($g_{l.MAX}$, β , and D_0) for the Leuning model (Table 1). Utilising the default parameter values for the Leuning model used in the CABLE land-surface model (for the evergreen broadleaf plant functional type), for example, led to severe under-prediction of g_s (Figure S3). In other words, with commonly used parameter values, the Leuning model would have performed worse than all other models tested here (BIC = -2479).

The model incorporating hydraulic limitation (Tuzet K-PSI) showed a good agreement (BIC = -2387) with observations at both low and high D (Figure 4 and Table 1). It achieved the second-best BIC value (Table 1). However, a comparison with the measured leaf water potential values shows that the Tuzet model performed well for the wrong reasons. The Tuzet K-PSI model predicted a decline of ψ_L with increasing D (Figure 5a); a large gradient between ψ_s and ψ_L (~ 4 MPa); and ψ_L values below ψ_{50} (< -5 MPa). None of these predictions were supported by the observations (Figure 5 a and b). The observed ψ_L did not change with D (Figure 5a) and remained above the point of onset of embolism in all measurements (Figure 5b). The minimum observed ψ_L value was -3.3 MPa, which was estimated to correspond to a PLC of 18%.

We examined the gas exchange data directly for evidence of non-stomatal limitation. Figure 6 shows the ratio of one-point V_{cmax} (estimated from gas exchange data using the “one-point”

method) to the predicted V_{cmax} at the same temperature (estimated from $A-C_i$ curves performed at a range of temperatures). This ratio declined strongly with increasing D as shown by data from EucFACE and Castlereagh sites. This decline in the one-point V_{cmax} clearly demonstrates that non-stomatal limitation is a factor in the decline of A at high D .

We then tested whether the non-stomatal limitation could be predicted as a function of leaf water potential (Tuzet V-PSI). Adding non-stomatal limitation to the Tuzet model comes at a cost of increased complexity, requiring six parameters to be fitted at the same time. This added complexity was not justified by the marginal improvements in R^2 resulting in the worst BIC value of all models tested (Table 1; Figure 7 a and b). Including the non-stomatal limitation in the Tuzet model did not lead to model improvement, which can be explained as follows. Firstly, we know that the plants did not reduce ψ_L sufficiently to cause cavitation and a reduction in hydraulic conductance (Figure 5). Therefore, the non-stomatal limitation as a function of ψ_L cannot predict a reduction in transpiration at high D . The observed decrease in g_s at high D leads to a less negative ψ_L at high D , and a less negative ψ_L implies a higher V_{cmax} . Higher V_{cmax} at high D contradicts both the assumption of non-stomatal limitation and the evidence shown in Figure 6.

Incorporating non-stomatal limitation into the Medlyn model (Medlyn V-D; Figure 7 c and d) improved the model predictions of both A and g_s (BIC = -2384). The Medlyn model, together with an empirical decline in V_{cmax} with D , achieved better R^2 values for both A and g_s than the more complicated models, resulting in the best BIC value (Table 1).

It is not possible to determine from our measurements what mechanism causes this reduction in apparent V_{cmax} . Following Zhou et al. (2013), we investigated the possibility that the reduction is largely attributable to a reduction in mesophyll conductance by estimating how large the reduction in g_m would need to be, to fully explain the observed reduction in one-point V_{cmax} . We assumed that all the discrepancy between the Medlyn model prediction and diurnal gas exchange data could be attributed to g_m . Then, for each diurnal measurement, a g_m value was estimated as that which minimized the difference between the model predictions and the diurnal observations. A reduction in g_m from 0.2 to 0.01 $\text{mmol m}^{-2} \text{s}^{-1}$ would be implied if non-stomatal limitation were entirely due to a reduction of g_m (Figure 8).

Stand scale model

Whole-tree transpiration estimated from sap flow measurements was used to evaluate the performance of the Medlyn V-D hypothesis at the whole-tree scale using the MAESPA model. The standard MAESPA using the Medlyn model overpredicted transpiration at EucFACE especially at high D (example of Ring 2 in Figure 9 a and b). The difference between the predicted and observed values increased strongly at high D (compare green with red dots in Figure 9b). However, after incorporating the Medlyn V-D model, MAESPA closely followed the seasonal variation of the measurements (Figure 7c) and agreed with observations across the full range of D . Overall, incorporating the Medlyn V-D model increased the coefficient of determination from 0.78 to 0.87 and reduced the root mean squared error (0.027 to 0.025; $L\ hr^{-1}$). The improvements were even larger at high D (>2.5 kPa) with a reduction of root mean squared error from 0.070 to 0.037. During the simulated year of 2013, incorporating non-stomatal limitation into MAESPA, resulted in a $\sim 19\%$ reductions in predicted annual transpiration ($59.7\ kg\ H_2O\ m^{-2}\ yr^{-1}$) and a $\sim 14\%$ reduction in gross primary production ($222.4\ g\ C\ m^{-2}\ yr^{-1}$). These findings indicate a large impact of non-stomatal limitation at high D .

We also explored whether the new model would improve predicted transpiration compared to observations at the Castlereagh site with similar species and climate conditions. Without canopy physiology or canopy structure data to parameterize the Castlereagh site, we took the approach of standardizing the observed sap flow and modelled E by their respective maxima and comparing the relationships of E with D (Figure 10). Both sites show a peaked relationship of E with D with the turning point occurring between 1-3 kPa, which agrees with the prediction of MAESPA incorporating non-stomatal limitation (red line in Figure 10).

Discussion

We evaluated a suite of commonly used g_s models and assumptions (hydraulic and non-stomatal limitation) used to represent the coupled A - g_s response to D at two native evergreen woodland sites in western Sydney. The observed decline of A and g_s at high D could not be captured with current widely-used models of stomatal conductance, and models were not improved by incorporating hydraulic limitation and xylem cavitation. The model incorporating a non-stomatal limitation (i.e., a reduction of apparent photosynthetic capacity

with increasing D) gave the best agreement with the observations at a large range of D . This finding highlights the importance of accounting for non-stomatal limitation in TBMs.

Standard models

Standard leaf gas exchange models, embedded within TBMs, perform poorly when D increases above 2.5 kPa, despite their wide use and important role (De Kauwe et al., 2015; Knauer et al., 2015). This finding is in line with previous studies showing the difficulties of modelling leaf gas exchange at high D (e.g., Farquhar, 1978; Franks et al., 1997; Eamus et al., 2008). Our analysis re-emphasises the need to improve leaf gas modelling in ecosystems that experience high D . The concerned regions include drylands, which cover 41% of the Earth's land surface (Reynolds et al., 2007) and potentially tropical, subtropical, and temperate ecosystems during dry seasons and heatwaves (Novick et al., 2016).

The comparison between the Leuning (1995) and Medlyn et al. (2011) models yields an important result, which is that improvements in the performance of the leaf gas exchange model at high D are unlikely to be achieved by varying the stomatal sensitivity to D . The Medlyn model does not have a mechanism that allows g_s or A to decrease at high D except via the temperature dependence of photosynthesis (Duursma et al., 2015; Kala et al., 2016). In contrast, the Leuning model does have a stronger regulation of g_s at high D but performs poorly at low D (Figure 3 and S3), and requires an additional parameter to achieve this compared to the Medlyn model. Nonetheless, neither model is able to capture both g_s and A at high D .

Models with hydraulic limitation

The decline of g_s at high D in the models incorporating hydraulic limitation is achieved either by a small hydraulic conductance (resulting from a very negative ψ_L) or by a small pressure gradient (resulting from a ψ_L close to ψ_s). The Tuzet model assumes the decline of ψ_L drives the reduction of g_s at high D . We found that this assumption led to an unrealistic decline in ψ_L with increasing D , contradicting ψ_L observations, which remained relatively consistent over the course of a day (Figure 5a). Moreover, the predicted ψ_L fell below the estimated ψ_{50} which is inconsistent with previous studies suggesting plant maintain ψ_L above the point of onset of xylem embolism (Sperry et al., 2002; Choat et al., 2012; Li et al., 2018).

Incorporating non-stomatal limitation allowed a ψ_L close to ψ_s at high D . However, a less negative ψ_L implied a higher V_{cmax} at high D which again contradicted the assumption of non-

stomatal limitation and the observations (Figure 6). As a result, the hydraulic limitation as implemented here, was unable to capture the observed D responses. Alternative models could potentially be more successful: Buckley (2013), for instance, proposed to model stomatal regulation via guard cell osmotic pressure in response to the water status of the surrounding epidermal cells. This approach is important because it can also incorporate increases in extra-xylary resistance that have been observed to occur in leaves (Yang and Tyree 1994; Scoffoni et al., 2017), roots (Cuneo et al., 2016), and the rhizosphere (North and Nobel, 1997). However, at this point the majority of models do not incorporate these resistances.

Plausible mechanisms of non-stomatal limitation

Studies on mesophyll conductance and photosynthetic capacity (e.g., Mediavilla et al., 2002; Nascimento and Marengo, 2013) have suggested the importance and mechanisms of non-stomatal limitation. The proposed mechanisms for non-stomatal limitation fall into two categories: (i) a biochemical-signalling-induced reduction in carboxylation capacity; or (ii) a reduction in mesophyll conductance, both of which have some empirical and theoretical support. Lawlor and Cornic (2002) and Lawlor and Tezara (2009) illustrated that carboxylation capacity is down-regulated at high water deficit due to reduction in adenosine triphosphate (ATP) synthesis. Huang et al. (2006) explored the cause of “midday depression” of g_s and A and suggested that the regulation of photosynthetic capacity is the likely explanation as plants aim to protect chloroplasts.

An alternative explanation for the decline of carboxylation capacity in the afternoon is sink limitation. It has been proposed that the accumulation of starch and sugar in the leaf over time causes an inhibition of photosynthesis (Paul and Foyer, 2001). We did not explore this effect because the data do not support this explanation at EucFACE (Wujeska-Klaue et al., 2019). We compared the diurnal time-course of photosynthesis for days with low and high D (Figure S9). On days with low D , there is no reduction in afternoon photosynthesis even though morning photosynthesis was high, indicating that the accumulation of starch and sugar is not strong enough to cause a reduction in photosynthetic capacity.

It is also possible that non-stomatal limitation is due to a reduction of mesophyll conductance (g_m) with increasing D . Flexas et al. (2008) examined our current understanding of the response of g_m to the environment (including D) and suggested that g_s and g_m could be co-regulated. Warren (2008) reported no g_m response to D in *Eucalyptus* seedlings. However,

that study only considered a small range of D (1 kPa to 2 kPa) which is not sufficient to show the decline observed here. We investigated how large the reduction in g_m would need to be to fully explain the observed reduction in apparent V_{cmax} and found that a reduction in g_m from 0.2 to 0.01 mmol m⁻² s⁻¹ would be implied if non-stomatal limitation were entirely due to a reduction of g_m (Figure 8). These values and magnitude of change of g_m are consistent with previous studies (Niinemets et al., 2009; von Caemmerer and Evans, 2015), suggesting that the apparent down-regulation could potentially be attributable to g_m . However, this result is not conclusive, because we are unable to quantify g_m with the data available.

Consequences for terrestrial biosphere models

This study showed that the current gas exchange models in TBMs can perform poorly at high D . TBMs thus may be improved by incorporating non-stomatal limitation to predict A and g_s more accurately at high D . Previous studies have recommended using non-stomatal limitation to improve modelled response to decreasing soil moisture availability (e.g., Keenan et al., 2010; Egea et al., 2011; Zhou 2013; De Kauwe et al., 2015). Knauer et al. (2019) further demonstrated that incorporating non-stomatal limitation significantly changed the predicted CO₂ response in TBMs. Here we suggest that incorporating non-stomatal limitation at high D may be necessary to capture the correct diurnal pattern of g_s and A as well as annual transpiration and gross primary production in ecosystems currently experiencing high D (>2 kPa) and likely to under future warming.

However, we showed that under current hydraulic limitation assumptions, non-stomatal limitation cannot be successfully linked to ψ_L . We applied a simple empirical relationship to estimate non-stomatal limitation with D , but without a good understanding of the underpinning mechanism or its generality, it is unclear how widely this empirical dependence could be used. Further studies at high D would be useful to quantify the impact of non-stomatal limitation more broadly, and to develop theoretical or mechanistic models (e.g., Gimeno et al., 2019). To inform mechanistic models of non-stomatal limitation, future studies need to collect extensive leaf gas exchange data across plant functional types under high D (>2 kPa). In addition, mechanistic studies are needed to elucidate the key processes underlying non-stomatal regulation, including changes in photosynthetic capacity and g_m . The empirical relationship describing non-stomatal limitation that we present here could be replaced with theoretical or mechanistic alternatives as they emerge.

Data and Materials Availability

The code and parameters of the models are freely available via https://github.com/Jinyan-Yang/Yang_2019_VPD.

Figure captions

Figure 1. (a) Soil water content (θ ; dimensionless) averaged over the top 150 cm of each ring and (b) Leaf Area Index (LAI) at EucFACE in 2013. The LAI data were estimated by Duursma et al. (2016) from measurements of PAR transmittance and smoothed with a generalized additive model. Warm (red, orange and brown) and cold (blue, cyan and navy blue) colours depict elevated and ambient CO_2 rings.

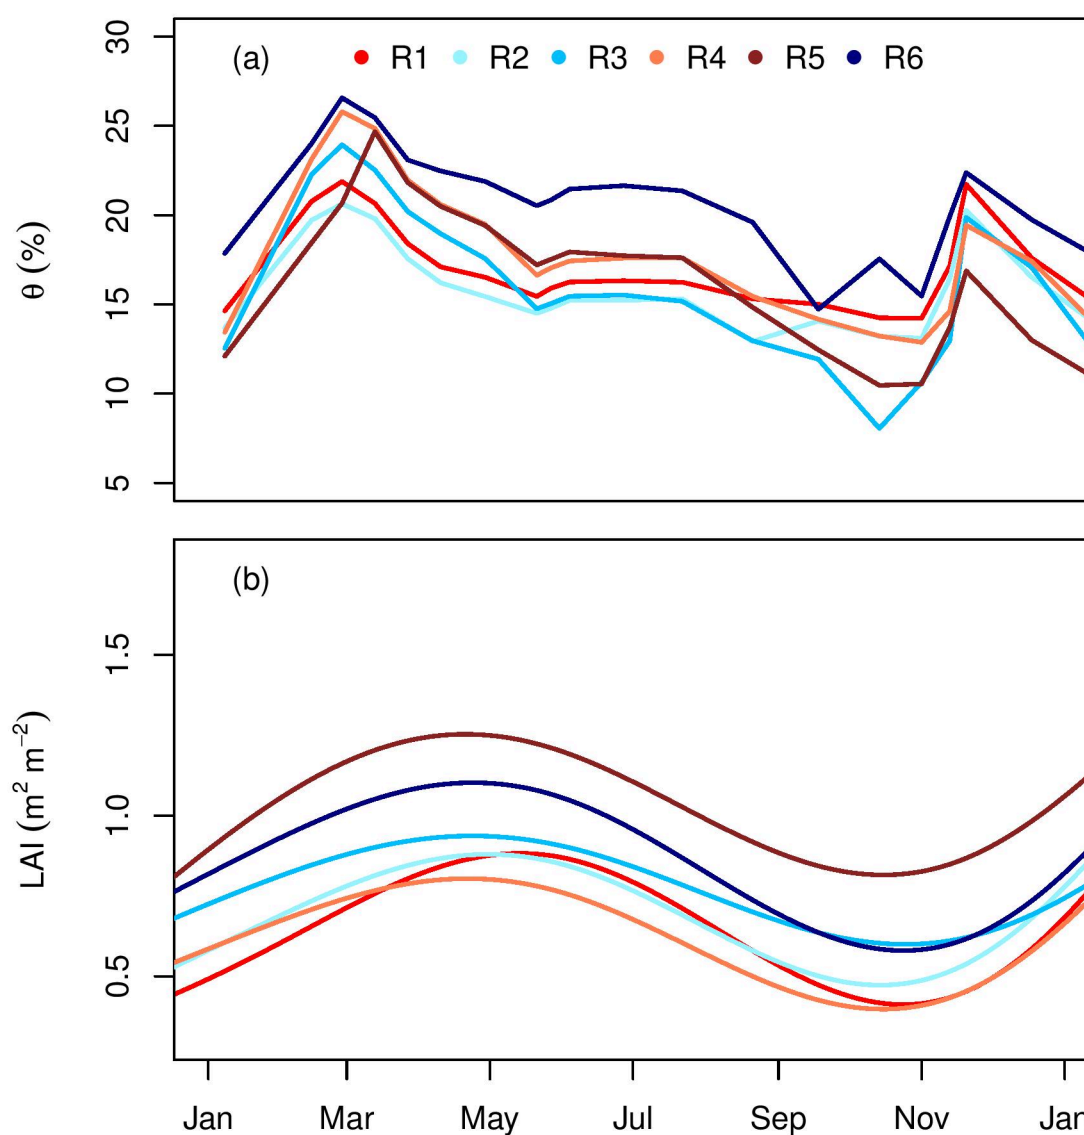

Figure 2. The observed response of light-saturated photosynthesis (A) and stomatal conductance (g_s , re-drawn from Gimeno et al. 2016) to vapour pressure deficit (D) in the Licor chamber at EucFACE. Data are leaf gas exchange from four campaigns in 2013 in all six rings (obtained from Gimeno et al. 2016). The chamber D is similar to that of the outside air. Open circles: Ambient (A) rings; Closed circles: Elevated (E) rings.

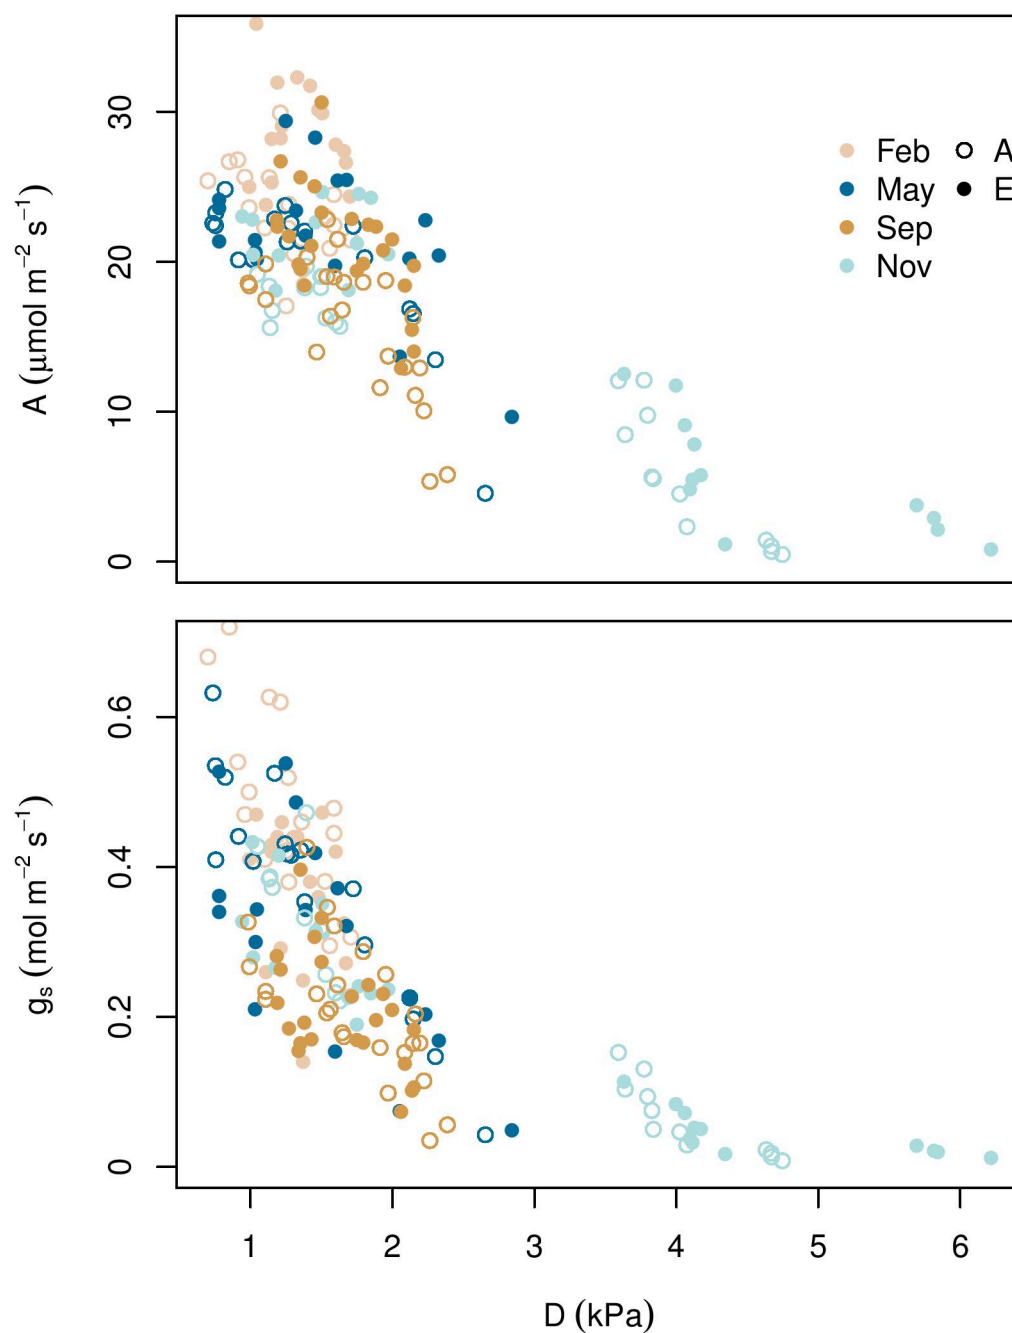

Figure 3. Modelled photosynthesis (A) and stomatal conductance (g_s) compared with observations. (a) and (b) Medlyn model (Eqn. 1). (c) and (d) Leuning model (Eqn. 2). Models were fitted to both A and g_s data.

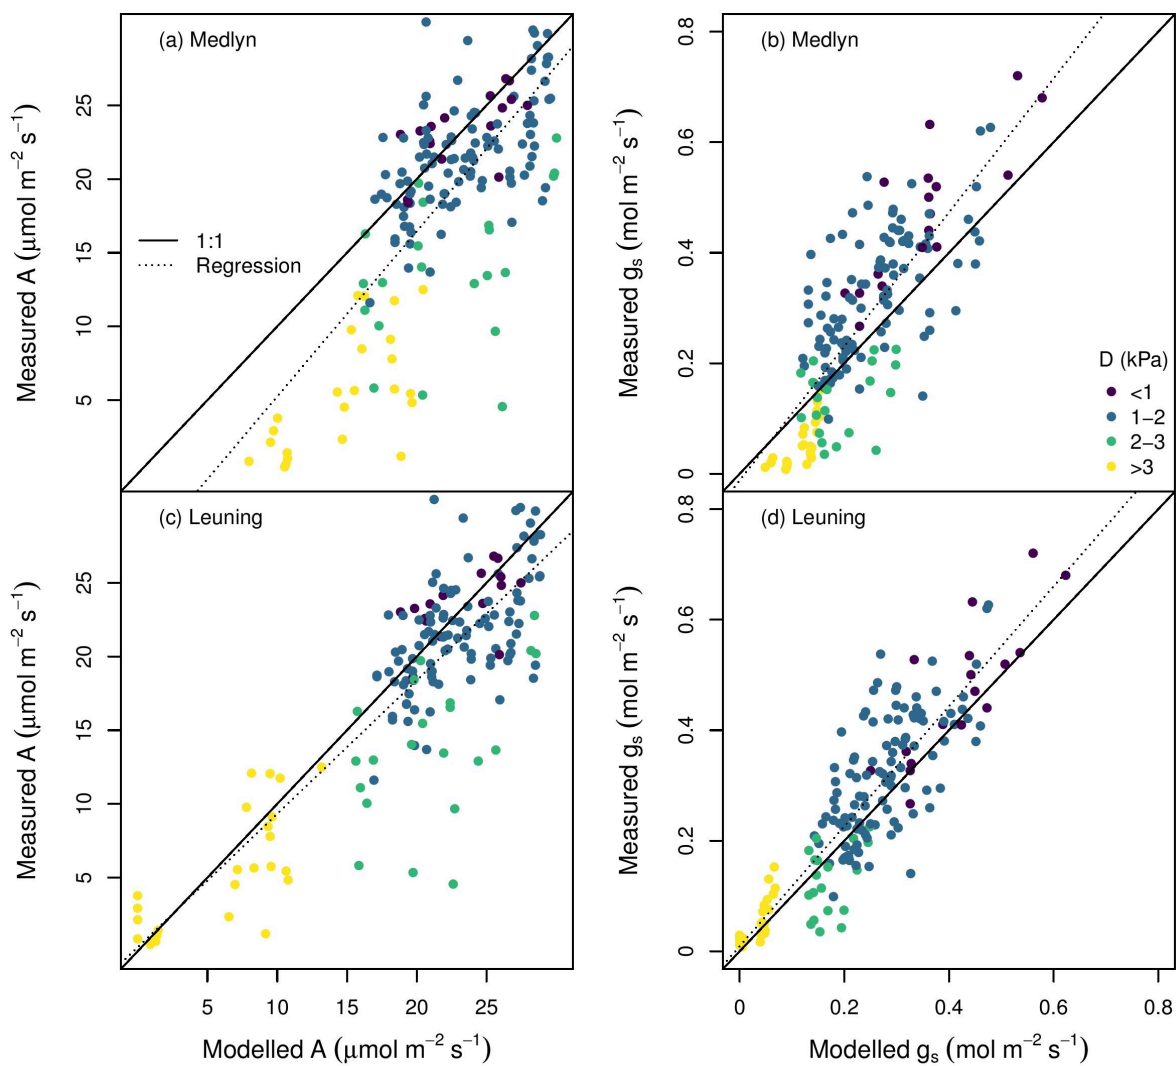

Figure 4. Modelled photosynthesis (A) and stomatal conductance (g_s) incorporating hydraulic limitation (Tuzet K-PSI, Eqns. 3-7) compared with observations.

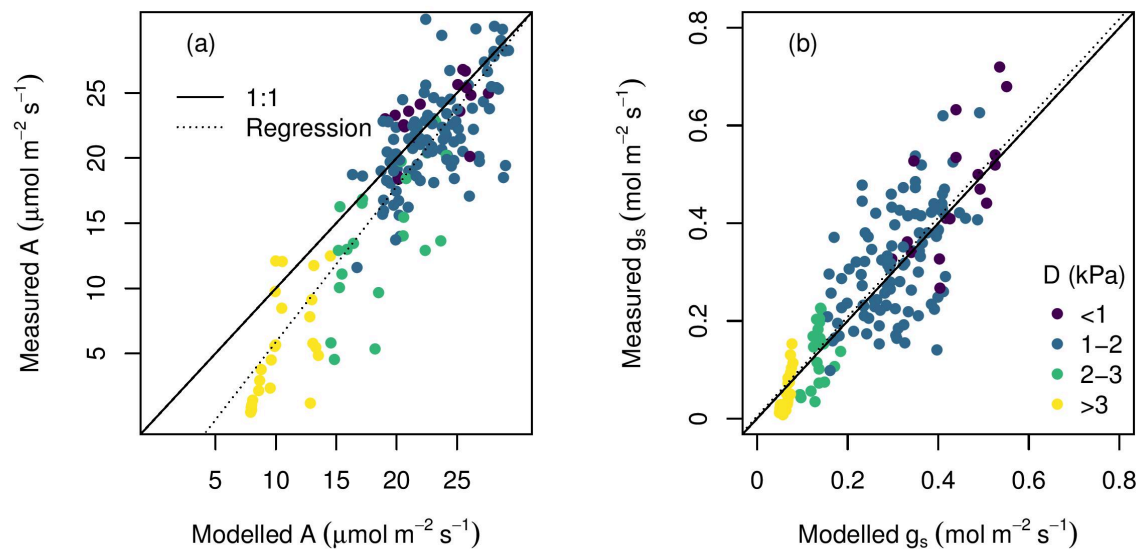

Figure 5. The Tuzet K-PSI model did not capture the observed leaf water potential (ψ_L). (a) Predicted and observed ψ_L (circles and crosses, respectively) from the Tuzet model. Observations were made mid-morning (lower D , shown in blue) or early afternoon (higher D , shown in orange). (b) Estimated PLC curve based on dehydration measurements. Note in (a) that observed ψ_L stays above the water potential corresponding to ~20% PLC (> -3 MPa), but the model predicts this value to fall to ~80% PLC (< -5 MPa).

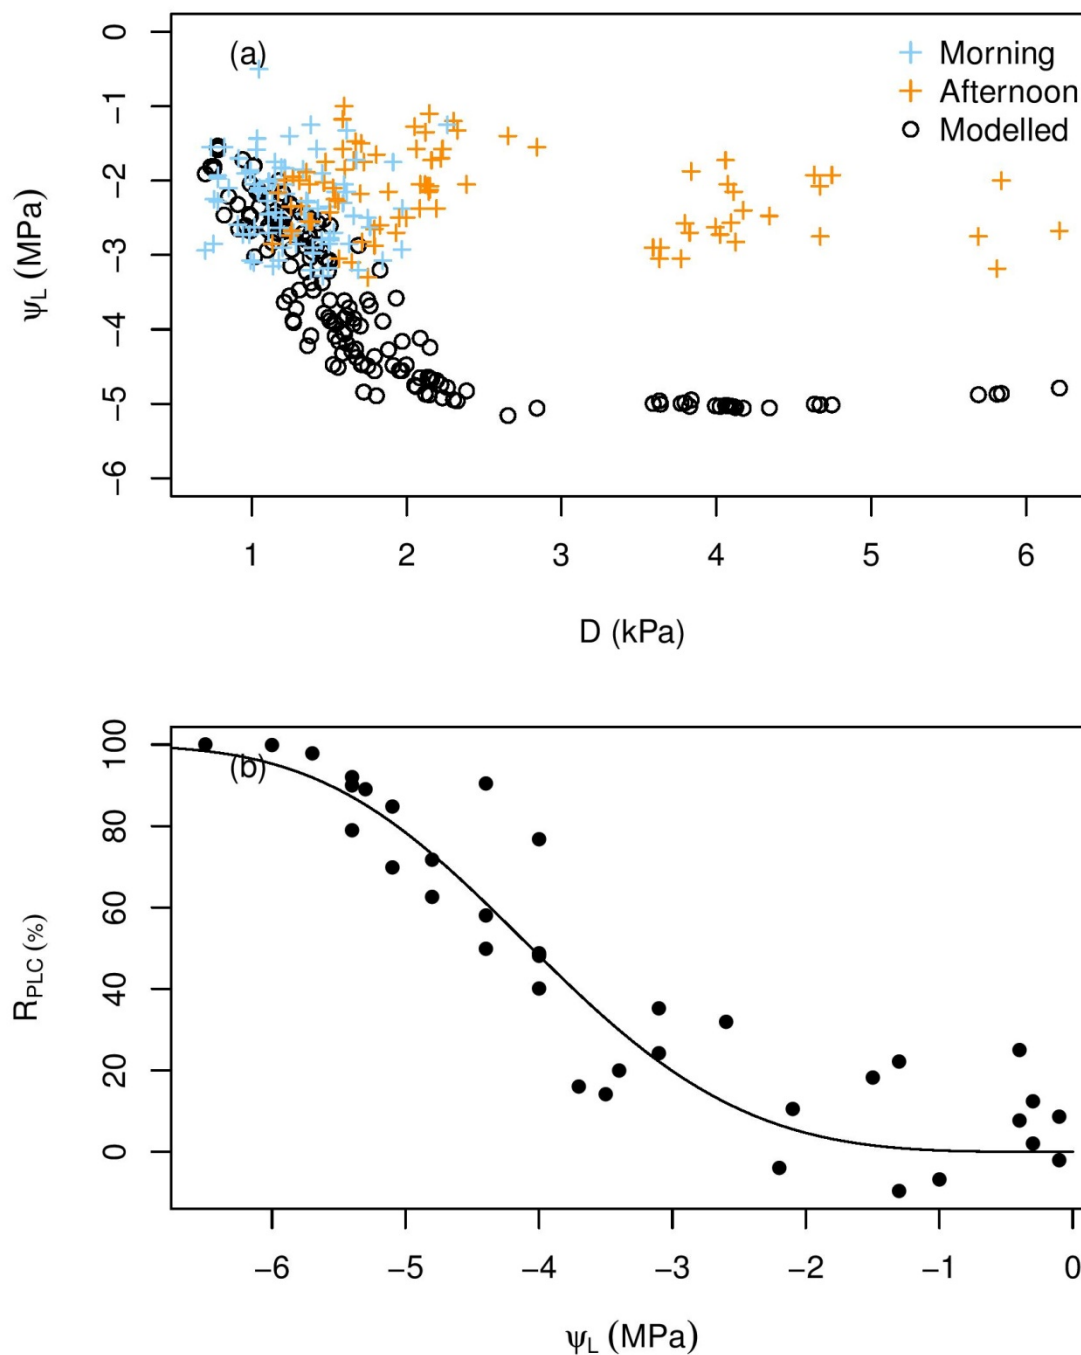

Figure 6. Ratio of one-point V_{cmax} (estimated from gas exchange data using the “one-point” method) to the predicted V_{cmax} at the same temperature (estimated from $A-C_i$ curves performed at a range of temperatures), as a function of D . EucFACE data (orange) are from Gimeno et al. (2016); Castlereagh data (blue) are from Zeppel et al. (2008). Only the EucFACE data are used in parameterization; the Castlereagh data are used to show that the pattern is consistent across sites in the area.

Figure 7. Modelled photosynthesis (A) and stomatal conductance (g_s) incorporating non-stomatal limitation (Eqn. 9) into Tuzet (Tuzet V-PSI) and Medlyn models (Medlyn V-D) compared with observations.

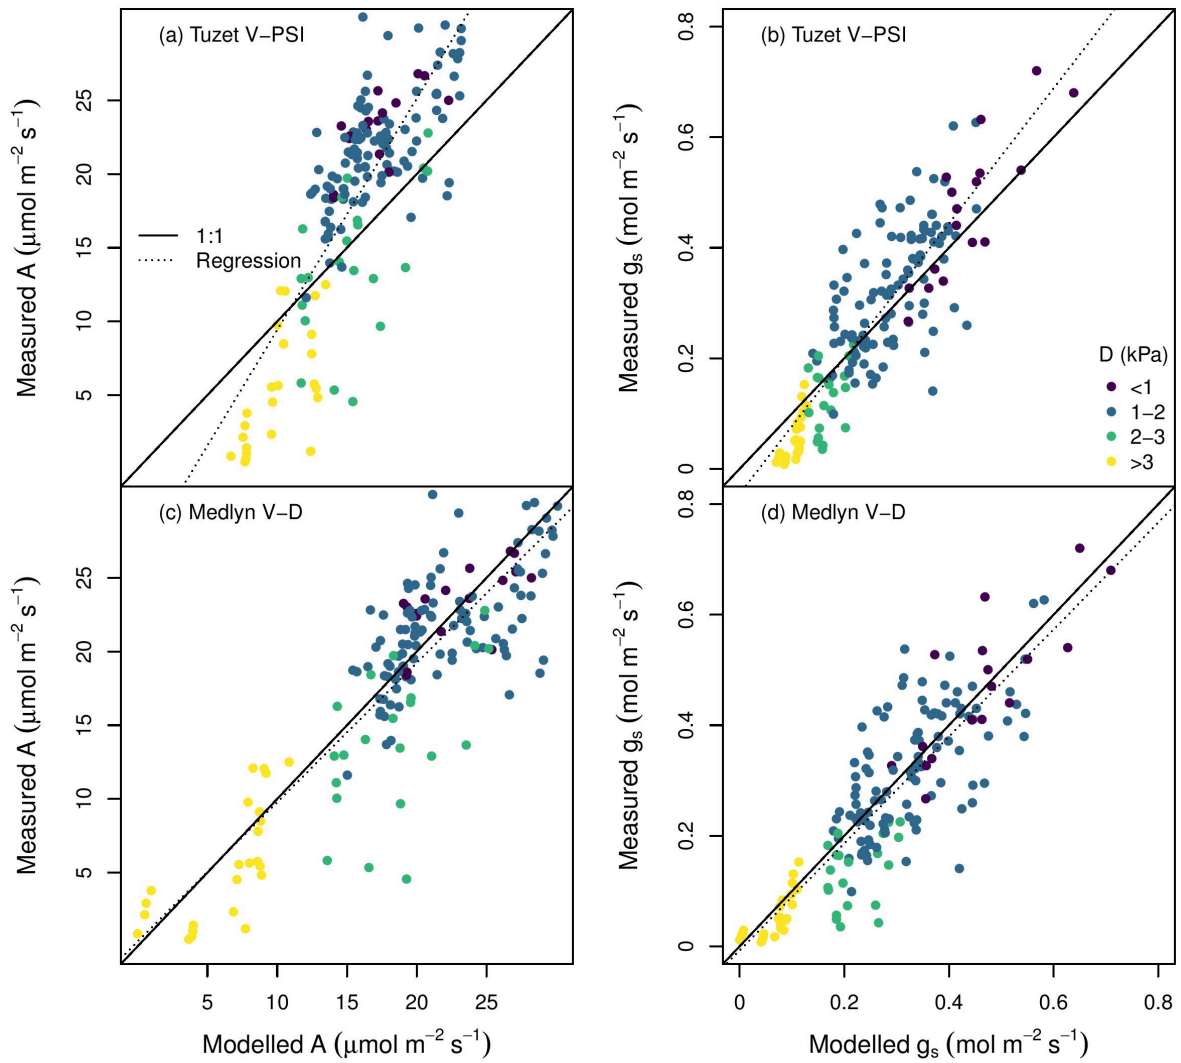

Figure 8. Estimated mesophyll conductance (g_m ; $\text{mol m}^{-2} \text{s}^{-1}$) shows a decline with increasing vapour pressure deficit (D ; kPa). The g_m is estimated from diurnal leaf gas exchange measurements in EucFACE during 2013 under the assumption that the observed decline in V_{cmax} is entirely due to decreasing g_m . The line marks the linear regression fit: $\ln(g_m) = -0.79 - 1.91 \cdot \ln(D)$ with a R^2 of 0.6. The fitting estimates a g_m of $0.12 \text{ mol m}^{-2} \text{ s}^{-1}$ at $D = 2 \text{ kPa}$; $0.03 \text{ mol m}^{-2} \text{ s}^{-1}$ at $D = 4 \text{ kPa}$.

Figure 9. Modelled transpiration (E) compared to sap flow estimated by heat pulse sensors (measured E). Data shown are daytime for one stand (Ring 2) in 2013. Other stands are similar (Figures S4-S8). Panels (a) and (b) show measured and modelled E over time from original MAESPA. Panels (c) and (d) show the result from MAESPA with V-D hypothesis. The solid lines in Panels (a) and (c) show the daily average while the shading shows hourly variation (standard deviation).

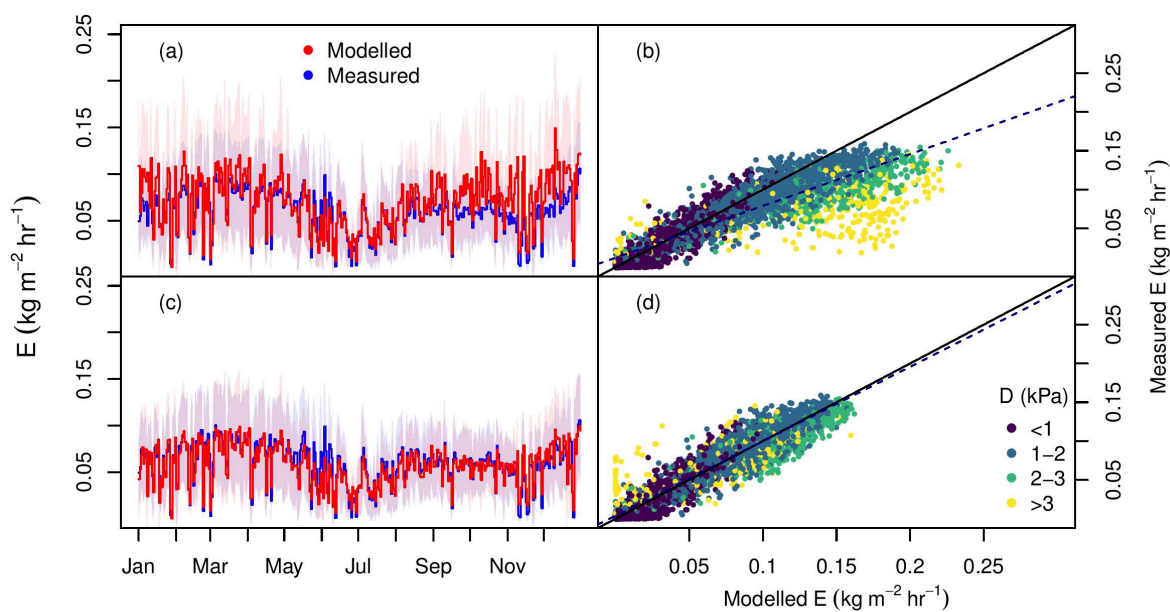

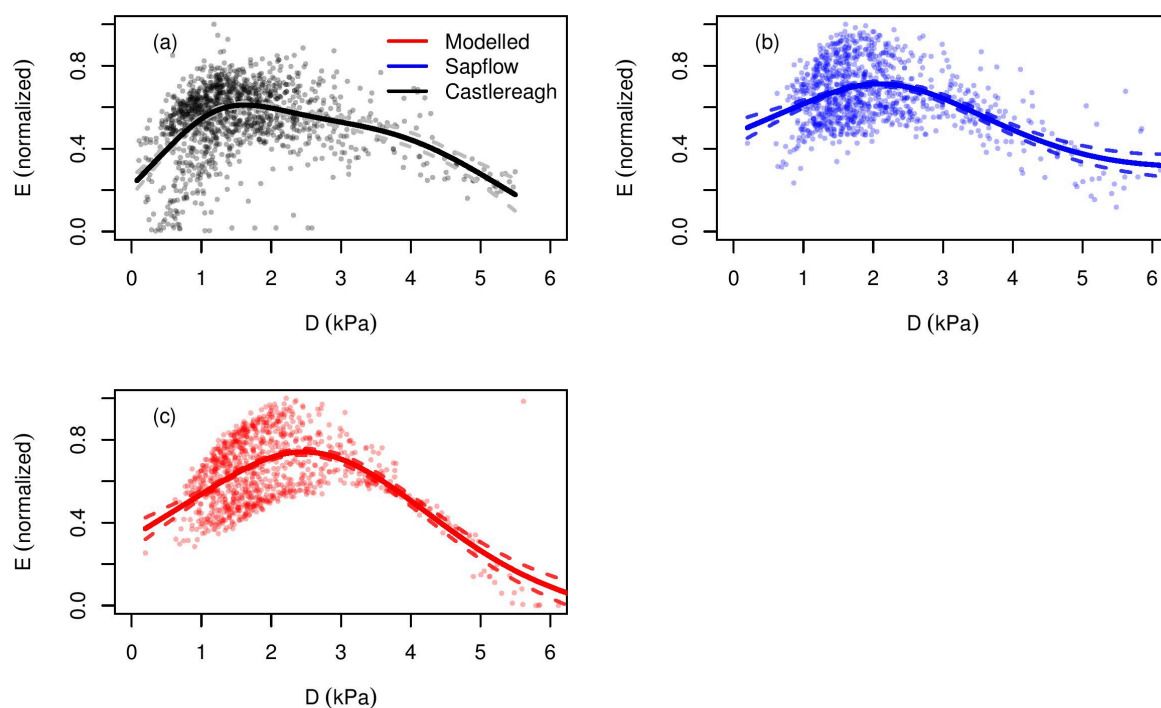

Figure 10. Transpiration (E) across different sources/sites as a function of vapour pressure deficit (D). (a) is the sap flow data from Castlereaigh (Zeppel et al., 2009). Bold line: generalised additive model ($df = 5$) fit to the data at saturated light (with PAR > 75% quantile). (b) and (c) are the estimated (sap flow) and modelled half-hourly daytime E for Ring 2 at EucFACE in 2013, respectively. Black and blue lines represent the same fitting to the modelled and sap flow data.

Tables

Table 1. Summary of model parameter values and performance considered in this study. Note the differences in meanings and units in g_i among models. Table shows both the coefficient of determination (R^2 ; higher is better) and inverse of Bayesian information criterion (BIC; lower is better) of both A and g_s . Each criterion is ranked for the best two model combinations (best and second best marked as dark and light shade). Units for parameters are as follows: $g_{l,max}$ and g_{IT} , $kPa^{0.5}$; β , unitless; D_0 , kPa ; ψ_f and ψ_{fv} , MPa ; s_f and s_{fv} , MPa^{-1} ; K_{max} , $mol\ m^{-2}\ s^{-1}\ MPa^{-1}$; c_D , kPa^{-1} .

g_s model	V_{cmax}/K_{max} model	Fitted parameters	R^2 of A	R^2 of g_s	-BIC
Medlyn (Eqn. 1)	V constant	$g_{l,max}=5.34$ $\beta = 1.34$ $g_{l,max} = 19.90$	0.54	0.62	2452
Leuning (Eqn. 2)	V constant	$\beta = 0.38$ $D_0 = 0.72$ $g_{IT}=8.95$	0.70	0.76	2411
Tuzet (Eqn. 3)	V constant $K = f(\psi_L)$ (Eqn. 6)	$\psi_f = -4.25$ $s_f = 2.28$ $K_{max} = 1.01$ $g_{IT}=12.83$	0.77	0.71	2387
Tuzet (Eqn. 3)	$V = f(\psi_L)$ (Eqn. 8) $K = f(\psi_L)$ (Eqn. 6)	$\psi_f = -1.56$ $s_f = 16.62$ $K_{max} = 3.98$ $\psi_{fv} = -3.42$	0.65	0.75	2397
Medlyn (Eqn. 1)	$V = f(D)$ (Eqn. 9)	$s_{fv} = 0.50$ $g_{l,max}=5.67$ $\beta = 0.56$ $c_D = 0.14$	0.77	0.74	2384
