## Abstract

Preventing neurodegeneration-associated disability progression in patients with multiple sclerosis (MS) remains an unmet therapeutic need. As remyelination prevents axonal degeneration, promoting this process in patients might enhance neuroprotection. In demyelinating mouse lesions, local overexpression of semaphorin 3F (Sema3F), an oligodendrocyte progenitor cell (OPC) attractant, increases remyelination. However, molecular targeting to MS lesions is a challenge. A clinically relevant paradigm for delivering Sema3F to demyelinating lesions could be to use blood-derived macrophages as vehicles. Thus, we chose transplantation of genetically modified hematopoietic stem cells (HSCs) as means of obtaining chimeric mice with circulating Sema3F-overexpressing monocytes. We demonstrated that Sema3F-transduced HSCs stimulate OPC migration in a neuropilin 2 (Nrp2, Sema3F receptor)-dependent fashion, which was conserved in middle-aged OPCs. While demyelinating lesions induced in mice with Sema3F-expressing blood cells showed no changes in inflammation and OPC survival, OPC recruitment was enhanced which accelerated the onset of remyelination. Our results provide a proof of concept that blood cells, particularly monocytes/macrophages, can be used to deliver pro-remyelinating agents “at the right time and place,” suggesting novel means for remyelination-promoting strategies in MS.

## Introduction

Halting the progression of neurological disability in patients with multiple sclerosis (MS) is a major challenge. MS frequently starts as a relapsing–remitting disease (RRMS), with neurological symptoms alternating with episodes of recovery. RRMS eventually evolves into progressive disease, characterized by the development of permanent neurological handicaps. A subset of patients directly enters the progressive phase (Lassmann, 2018).

Currently used treatments for MS are mostly immunomodulators and immunosuppressants. These reduce inflammation and related relapses but are largely ineffective in preventing transition into progressive disease (Lassmann, 2018) where accumulation of disability is the consequence of neuronal/axonal loss, likely triggered by increased vulnerability of demyelinated axons (Kornek *et al*, 2000). Remyelination (myelin regeneration) of demyelinated axons protects these from degeneration, as shown by neuropathological studies of MS tissue (Kornek *et al*, 2000), experiments using a model of demyelination (Irvine & Blakemore, 2008), and myelin PET imaging of MS patients (Bodini *et al*, 2016). Hence, developing remyelination-promoting strategies is a major therapeutic goal to prevent progression in patients with MS (Lubetzki *et al*, 2020).

In a subset of MS lesions, remyelination failure is associated with depletion/low numbers of oligodendroglial cells (Boyd *et al*, 2013; Moll *et al*, 2013; Tepavčević *et al*, 2014; Heß *et al*, 2020). In these, stimulating oligodendrocyte progenitor cell (OPC) repopulation/recruitment to demyelinated areas appears crucial to enhance remyelination and achieve neuroprotection.

OPC recruitment in experimental lesions can be achieved by locally injecting a viral vector overexpressing a guidance molecule semaphorin 3F (Sema3F), an OPC attractant (Piaton *et al*, 2011; Boyd *et al*, 2013). Moreover, we previously showed that OPCs in

MS lesions express Sema3F receptor, neuropilin 2 (Nrp2), and that while Sema3F is detected in early lesions, it is not expressed in chronically demyelinated lesions (Williams *et al*, 2007). Thus, these data suggest that OPC recruitment in MS lesions may be enhanced by increasing intralésional Sema3F expression. However, the viral vector injection paradigm is not applicable in the patient setting for a number of reasons, one of them being that MS lesions are disseminated within the CNS. This question of how to optimally deliver therapeutic molecules to demyelinating MS lesions applies not only to strategies to increase OPC recruitment but also to other neuroprotective approaches such as delivering neurotrophic or antioxidative molecules to protect the axons, and in general, to any attempts to modify intralésional events in order to stop the progression of the pathology.

In leukodystrophies, a group of diseases in which a molecular defect in glial cells leads to anomalies in white matter formation and/or maintenance, intraparenchymal delivery of therapeutic proteins has been achieved using transplantation of autologous genetically modified hematopoietic stem/progenitor cells (HSCs). Using this strategy, blood-born cells engineered to overexpress the missing brain protein were reported to infiltrate the brain, which raised parenchymal levels of the protein in question and corrected, at least in part, the associated myelin pathology. This approach has been successful in both mouse models and human leukodystrophy patients (Biffi *et al*, 2004, 2006, 2013; Cartier *et al*, 2009; Sessa *et al*, 2016; Eichler *et al*, 2017).

We hypothesized that intralésional targeting of therapeutic molecules using blood-born cells could be a clinically relevant strategy to stimulate remyelination in demyelinating CNS diseases, such as MS, by means of targeting the expression of Sema3F to demyelinating lesions and increasing OPC recruitment.

We first showed that monocytes/macrophages derived from transplanted HSCs efficiently infiltrate demyelinating mouse lesions. We then designed lentiviral vectors that allowed us to genetically modify HSCs to overexpress Sema3F and investigated whether these cells can stimulate OPC migration *in vitro*, as well as OPC recruitment to demyelinating lesions and remyelination *in vivo*. We showed that the supernatant of Sema3F-transduced HSCs increases migration of young and middle-aged OPCs *in vitro* in Nrp2-dependent manner, and that chimeric mice with Sema3F-overexpressing blood cells show increased OPC recruitment and accelerated onset of remyelination. Thus, we conclude that genetically modified blood cells, particularly macrophages, can be used to efficiently and quickly express pro-remyelinating molecules in demyelinating lesions and promptly stimulate myelin repair.

Our results represent a proof of concept that genetically- = modified monocytes/macrophages can be used to enhance CNS remyelination, which provides novel cues for therapies to prevent/diminish neurological disability in patients with MS.

## Results

### Donor-derived macrophages infiltrate demyelinating lesions

To investigate whether transplant-derived cells target demyelinating CNS lesions, we injected preconditioned mice with whole bone marrow (WBM) isolated from actin-GFP mice (Fig 1A). At 2 months

post-transplant,  $72.6 \pm 5.8\%$  of blood cells were GFP<sup>+</sup>. Moreover,  $87.07 \pm 9.7\%$  of blood CD11b<sup>+</sup> cells (monocytes) were GFP<sup>+</sup>. Thus, monocytes in chimeric mice derive mostly from transplanted cells (Fig 1B).

We next induced demyelination in the spinal cord of chimeric mice by injecting lysolecithin (LPC) (Fig 1Ci).

At both 3 and 7 days post-lesion (dpl) (ongoing OPC recruitment), GFP<sup>+</sup> cells were found in demyelinated areas, and were CD11b/CD68<sup>+</sup> (macrophage marker) (Fig 1Cii–Civ). Quantification revealed that  $91.5 \pm 1.6\%$  of GFP<sup>+</sup> cells were macrophages. Moreover,  $47.5 \pm 4.6\%$  of macrophages in the lesion were GFP<sup>+</sup>. Because 96.35% (median) of circulating blood monocytes were GFP<sup>+</sup>, we assume that within lesions, all blood-derived cells are GFP<sup>+</sup>, while resident microglia/macrophages are GFP<sup>-</sup>, and thus conclude that both resident and blood-derived macrophages are recruited early to LPC lesions.

Therefore, graft-derived macrophages reliably target CNS lesions early after demyelination and hence represent appropriate molecular vehicles for stimulating OPC repopulation/myelin repair.

### Genetically modified HSCs secrete Sema3F that increases OPC migration

Next, we generated lentiviral vectors to overexpress Sema3F. We used a bicistronic construction with self-cleaving T2A sequence inserted between Sema3F- and GFP-encoding sequences, all under PGK promoter (PGK-GFP-T2A-Sema3F; Appendix Fig S1). Thus, Sema3F and GFP should be produced as separate proteins.

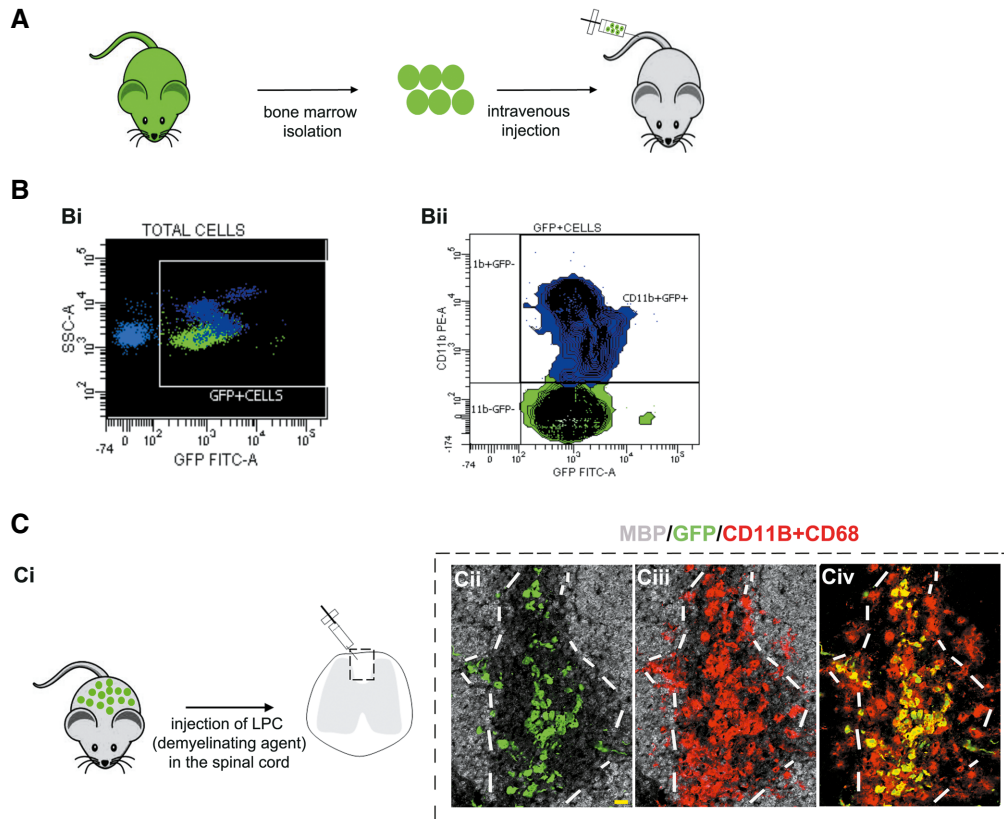

Next, we genetically modified HSCs to overexpress Sema3F. HSCs were isolated, transduced with PGK-GFP-T2A-Sema3F or PGK-GFP lentiviral vectors, and expanded for 5 days (Fig 2A).  $35.8 \pm 5.3\%$  of PGK-GFP-T2A-Sema3F- and  $76.7 \pm 4.8\%$  of PGK-GFP-transduced cells were GFP<sup>+</sup> (Fig 2B). This difference in transduction efficiency can be explained by a 30% greater size of Sema3F-GFP transgene (Appendix Fig S1).

Using western blot, we detected GFP expression in the lysates of both control and Sema3F-transduced cells, although to a lesser extent in the latter (Fig 2C), consistent with lower transduction efficiency of PGK-GFP-T2A-Sema3F. Sema3F was detected exclusively in the supernatant of PGK-GFP-T2A-Sema3F-transduced cells (Fig 2C).

Cell viability (propidium iodide and Viability Dye labeling) and the pattern of colony formation (proliferation/differentiation potential) were similar between GFP- and Sema3F-transduced HSC preparations (Appendix Fig S2).

To verify the functionality of Sema3F secreted by HSCs, we used transwell chamber assay and quantified migration of adult OPCs in response to the supernatant from non-transduced (NT)-, PGK-GFP-(GFP), or PGK-GFP-T2A-Sema3F-transduced (Sema3F-GFP) HSCs (Fig 2D). Migration was twofold higher in Sema3F-GFP versus GFP (Fig 2E), which was similar to the increase in migration induced by a recombinant Sema3F at 500 ng/ml (2.2-fold compared to control, Fig 2E). An increase in OPC migration was also observed in experiments using supernatants from PGK-GFP-T2A-Sema3F- or PGK-GFP-transduced HEK cells.

The increase in migration induced by the supernatant from Sema3F-GFP-transduced HSCs was abrogated in the presence of anti-Nrp2 function-blocking antibody. Similar findings were obtained for recombinant Sema3F (Fig 2E). Thus, Sema3F-GFP-

transduced HSC supernatant increases OPC migration *in vitro* in Nrp2-dependent manner.

Therefore, while transduction with PGK-GFP-T2A-Sema3F does not affect HSC viability or differentiation *in vitro*, it leads to secretion of Sema3F that increases OPC migration, via Nrp2.

### OPCs from both young and middle-aged mice are attracted by Sema3F

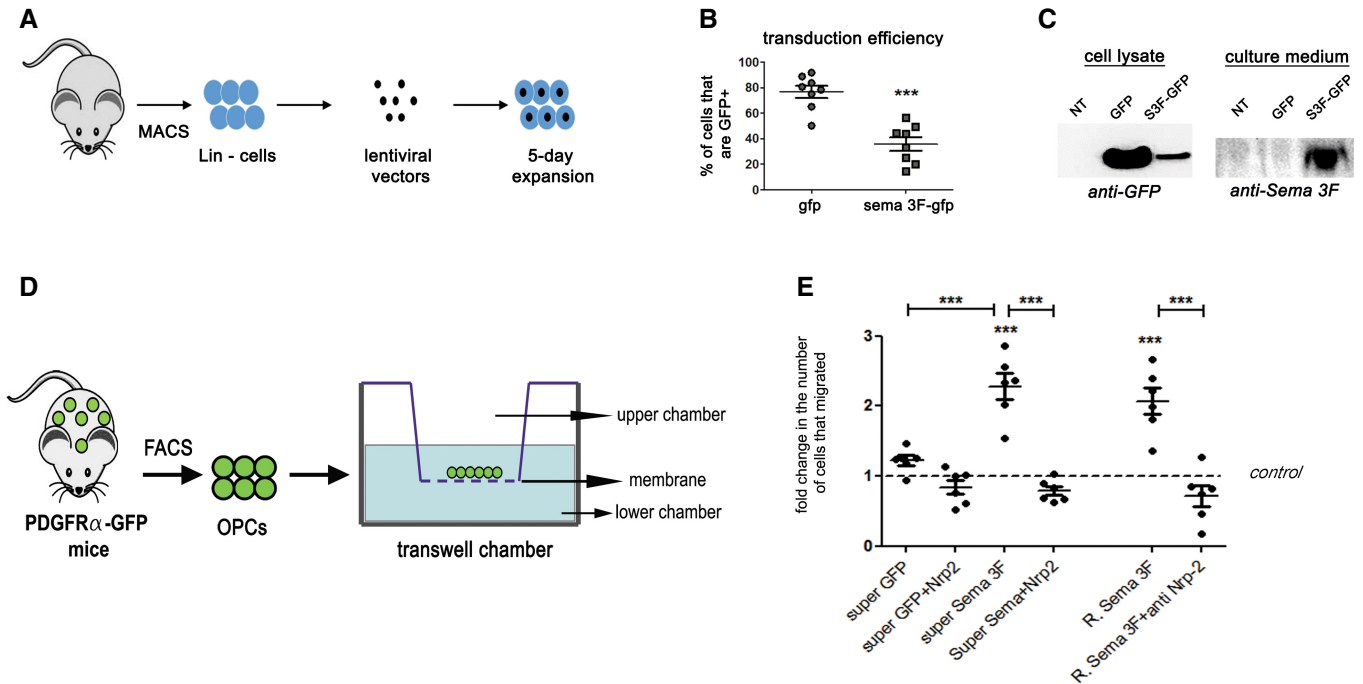

Next, we investigated whether the responsiveness of OPCs to Sema3F decreases with age. We first checked whether aged OPCs retain Nrp2 expression. Both microarray data on FACS-sorted OPCs from the brains of PDGFR $\alpha$ -GFP mice (Fig 3A) and RNA-sequencing data on oligodendroglial spinal cord cells (Fig 3B) demonstrated a lack of statistically significant changes in Nrp2 mRNA expression between 2-month-old (young) and 12-month-old (middle-aged) mice. Interestingly, immunohistochemical analyses of Sema3F expression in LPC lesions at 4 dpl (Fig 3C–E) and 7 dpl showed a significant decrease in Sema3F-expressing cells in lesions induced in middle-aged and old (18-month-old) mice at 4 dpl (onset of OPC recruitment), as compared to young mice (Fig 3F), which was

partially due to a decrease in microglial/macrophage Sema3F expression (Fig 3G). We then evaluated whether recombinant Sema3F or the supernatant from PGK-GFP-T2A-Sema3F-transduced cells retains its capacity to attract OPCs with age. We exposed OPCs FACS sorted from the brains of young versus middle-aged PDGFR $\alpha$ -GFP mice to recombinant Sema3F- or PGK-GFP-T2A-Sema3F-transduced cell culture supernatant in a Boyden transwell chamber for 24 h. Our results show that OPCs isolated from middle-aged mice are mobilized by both recombinant Sema3F and supernatant-derived PGK-GFP-T2A-Sema3F-transduced cell supernatant (Fig 3H). We have not performed migration experiments with OPCs isolated from old (18 months of age) mice because, using FACS sorting, we obtain very low numbers of cells, insufficient for migration experiments.

Thus, OPCs from middle-aged mice retain the expression of Nrp2 gene and are attracted by Sema3F.

### Hematopoietic reconstitution by transduced HSCs

We transplanted female GFP and Sema3F-transduced HSCs (a mixture of transduced and non-transduced cells) to preconditioned male mice

(GFP and Sema3F mice; Fig 4A). At 2 months post-grafting, qPCR for sex-containing region of the Y chromosome showed extensive reconstitution by transplanted (female) cells in both groups (87.96 ± 4.05% GFP and 88.68 ± 2.41% Sema3F) (Fig 4B). Flow cytometry analyses of GFP expression revealed 73.8 ± 3.1% of GFP<sup>+</sup> (transgene-carrying) cells in GFP and 22.9 ± 2.1% in Sema3F group (Fig 4C), consistent with lower transduction efficiency of PGK-GFP-T2A-Sema3F vector mentioned above.

Using flow cytometry, we analyzed differentiation of transduced (GFP<sup>+</sup>) cells into monocyte (CD11b<sup>+</sup>), B-cell (CD19<sup>+</sup>), and T-cell (CD3<sup>+</sup>) lineages. Interestingly, the percentage of GFP cells co-expressing CD11b was higher in Sema3F mice, while that co-expressing CD19 was lower (Fig 4D). However, this difference did not affect the blood cell composition in chimeric mice as the percentages of total CD11b<sup>+</sup>, CD19<sup>+</sup>, and CD3<sup>+</sup> cells in the blood were similar between the two groups and comparable to that of

control (non-treated) mice (Fig 4E). Therefore, Sema3F mice show normal blood composition.

We then analyzed whether Sema3F modifies GFP<sup>+</sup> cell numbers in the heart, liver, lung, and spleen. We detected numerous GFP<sup>+</sup> cells in the spleen, as expected. We also detected GFP<sup>+</sup> cells in the lungs, albeit at lower numbers as compared to the spleen. Correlation analyses revealed that these numbers were determined by the GFP chimerism in the blood ( $r = 0.84$  spleen,  $r = 0.94$  lung), which indicated that Sema3F expression did not alter GFP<sup>+</sup> cell homing and maintenance in these organs.

#### Sema3F-carrying cells successfully target demyelinating lesions and are predominantly macrophages

We investigated the response of transgene-carrying cells to LPC-induced spinal cord demyelination. GFP<sup>+</sup> cells were detected at 7 and 10 dpl in GFP and Sema3F mice with less cells in the latter, although this difference was not statistically significant (Fig 5A and B, D and E, G). Using Prism, we detected a strong correlation between the percentage of GFP<sup>+</sup> cells in the blood and numbers of GFP<sup>+</sup> cells in lesions at both 7 ( $r = 0.88$ ) and 10 dpl ( $r = 0.81$ ). This indicates that numbers of GFP<sup>+</sup> cells in the lesions are determined by GFP blood chimerism, itself dependent on transduction efficiency

(lower for PGK-GFP-T2A-Sema3F). Therefore, Sema3F expression does not alter monocyte homing to demyelinating CNS lesions.

We analyzed whether recruited cells persist in the lesions at late time points. At 60 dpl, GFP<sup>+</sup> cell numbers decreased compared to earlier time points in both GFP and Sema3F mice (GFP mice: Kruskal–Wallis test for GFP<sup>+</sup> cells at 7, 10, and 60 dpl:  $P = 0.0079$ ; Sema3F-GFP mice: Kruskal–Wallis test at 7, 10, and 60 dpl:  $P = 0.0252$ ; significant difference between 7 and 60 dpl, Dunn's multiple-comparison test). There were no significant differences in the numbers of GFP<sup>+</sup> cells between the two groups at any of the time points analyzed (Fig 5C, F and G). However, we could only analyze two GFP and three Sema3F chimeras, so we cannot deduce whether Sema3F-expressing cells are differentially retained in the CNS.

Co-immunolabeling with GFP and microglia/macrophage marker Iba1, T-cell marker CD3, and B-cell marker CD45R/B220 revealed that the absolute majority of GFP<sup>+</sup> cells were macrophages (median range across all groups tested 91.67–100%) (Fig 5H–M, T). Total Iba1<sup>+</sup> cell numbers (infiltrating and resident macrophages + microglia) were similar in GFP versus Sema3F mice (Fig 5U), inferring that total myeloid infiltration was unchanged between these two groups. These numbers progressively decreased in time, as expected. Importantly, myelin debris removal (performed by

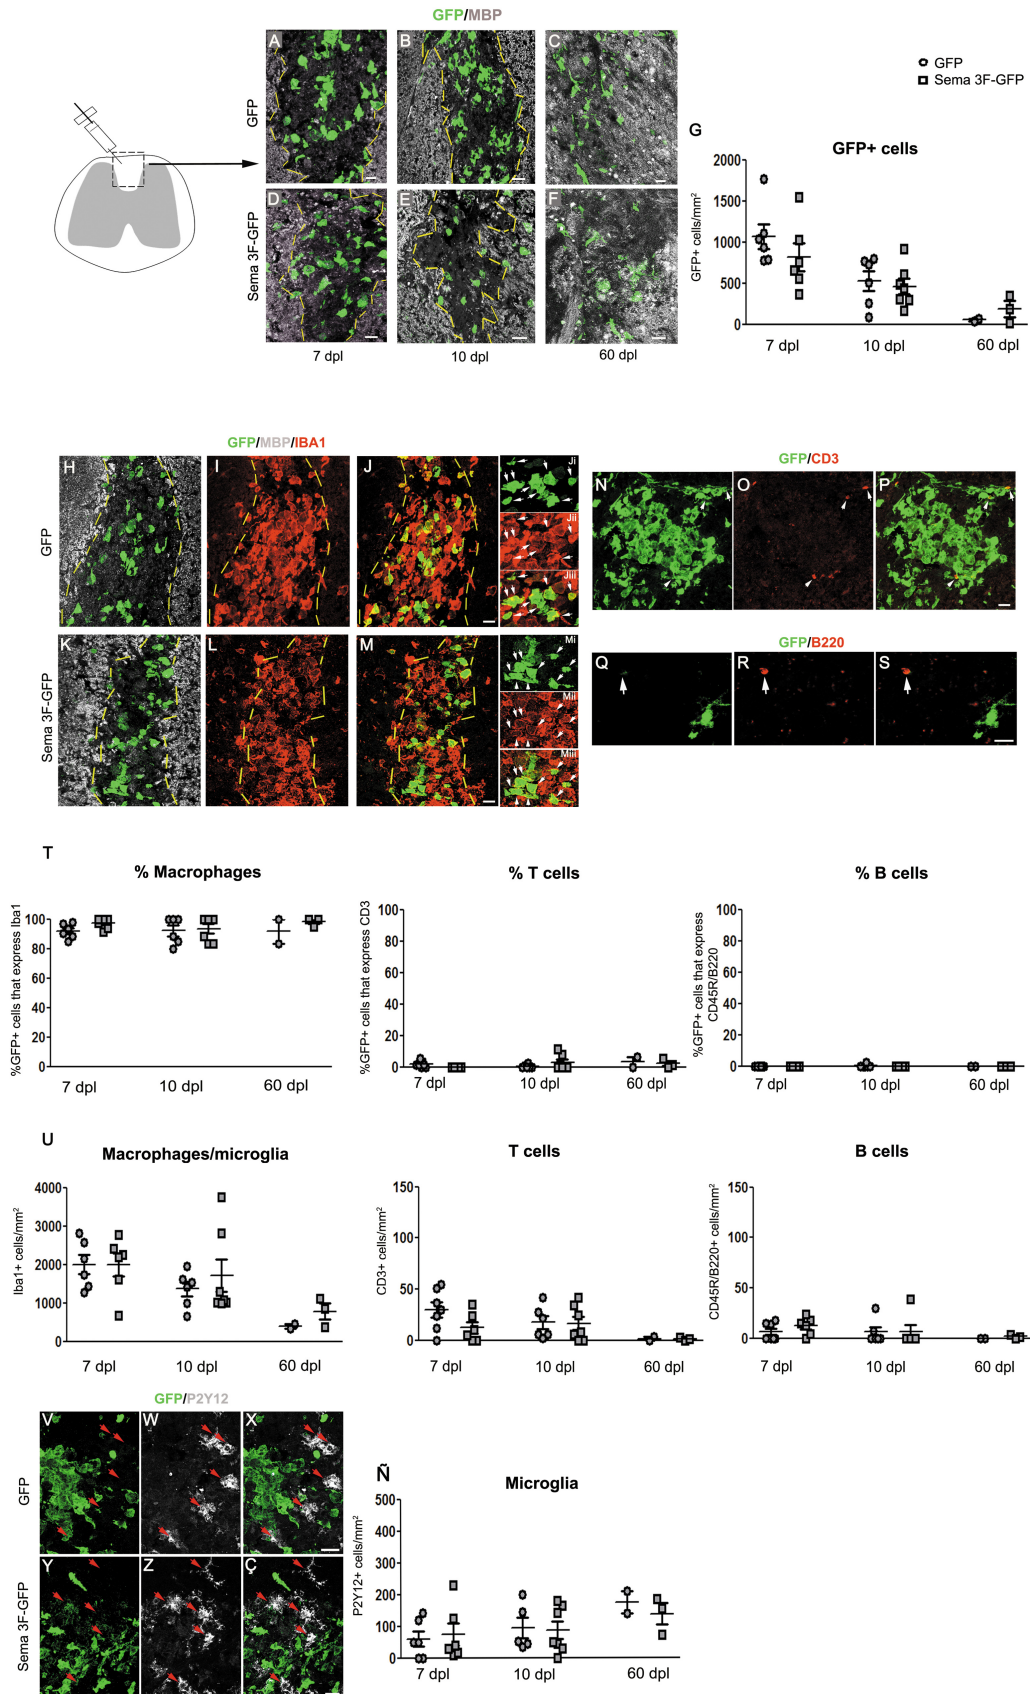

Figure 5.

- U Quantification of Iba1<sup>+</sup>, CD3<sup>+</sup>, and B220<sup>+</sup> cells. For all three populations, no significant differences in cell numbers were observed between GFP and *Sema3F* mice, and a general decrease was observed at 60 dpl compared to earlier time points.
- V–Ç Co-labeling for GFP and microglial marker P2Y12. Red arrows indicate P2Y12<sup>+</sup> cells. Exclusion between the two markers is obvious in both groups.
- Ñ Quantification of P2Y12<sup>+</sup> cells. No significant changes are observed between the groups or across the time.

Data information: For all figure panels,  $n = 6–7$  mice/group for 7 and 10 dpl,  $n = 2–3$  mice/group for 60 dpl. Mean  $\pm$  SEM. Scale bars 20  $\mu$ m, except for S (10  $\mu$ m).

Source data are available online for this figure.

macrophages/microglia) did not appear different between GFP and *Sema3F* chimeras, as evidenced by Oil Red O staining at 7 dpl (Appendix Fig S3).

Small numbers of GFP<sup>+</sup> T cells were also detected in the lesions of both GFP and *Sema3F* chimeras (Fig 5N–P, T, U). B cells were observed mostly in the meninges, in low numbers, and very few, that were GFP<sup>−</sup>, were also found in the spinal cord parenchyma at 7 dpl (Fig 5Q–S, T, U). No changes were detected in the total numbers of infiltrating CD3<sup>+</sup> and B220/CD45<sup>+</sup> cells between GFP and *Sema3F* chimeras at any of the time points analyzed (Fig 5T).

We then investigated whether *Sema3F* overexpression by infiltrating cells altered numbers of microglial cells in lesioned areas by performing immunohistochemistry for microglial marker P2Y12. In both groups, we observed a clear distinction between GFP<sup>+</sup> and P2Y12<sup>+</sup> cells (Fig 5V–Ç), the latter observed preferentially around lesion borders and outside the lesion. Unlike the numbers of GFP<sup>+</sup> cells or total Iba1<sup>+</sup> cells, the numbers of P2Y12<sup>+</sup> cells did not decrease with time (Fig 5Ñ). However, it is possible that not all microglial cells were detected by P2Y12 labeling because, under certain pathological circumstances, these downregulate markers such as P2Y12 and TMEM119 (Butovsky & Weiner, 2018).

Thus, the absolute majority of transgene-carrying cells in LPC lesions are macrophages, which is consistent with previous reports showing scarce lymphocytic infiltration in toxin-induced demyelinating lesions (Graça & Blakemore, 1986; Tepavcević & Blakemore, 2005, 2006). In addition, the inflammatory status of LPC lesions in *Sema3F* chimeras is comparable to that of the control mice.

Interestingly, while basically all GFP<sup>+</sup> cells at 7 and 10 dpl had morphology of myelin-phagocytosing macrophages (large, round), we also observed ramified GFP<sup>+</sup> cells in the lesion-neighbor tissue at all time points and within the lesion at 60 dpl (Appendix Fig S4). This suggests that blood-derived myeloid cells (i) adopt microglia-like morphology in response to CNS milieu and (ii) that a small portion of infiltrating cells remains in the CNS once lesions have remyelinated.

#### Lesions in *Sema3F* mice show increased OPC recruitment

We then investigated whether *Sema3F* overexpression by blood-derived cells in demyelinating lesions affects OPC repopulation of the lesion. Numbers of the PDGFR $\alpha$ <sup>+</sup> (OPCs) and Olig2<sup>+</sup>

(oligodendroglia) cells were quantified at 7 and 10 dpl, as OPC recruitment/proliferation is maximal within this time window (Fig 6A), and were significantly higher in *Sema3F* mice at 7 dpl (Fig 6B–D, E–G). Close proximity of OPCs and transgene-carrying macrophages in the lesions of *Sema3F* mice was revealed using 3D reconstructions (Fig 6E'–F'). We investigated whether increased OPC numbers correlated with increased OPC proliferation in the lesions. Co-immunolabeling for Nkx2.2 (marker of reactive OPCs) and proliferation marker Ki67 showed that numbers of total Nkx2.2<sup>+</sup> cells (Fig 6H–I, J) were significantly higher in the lesions of *Sema3F* mice as compared to GFP mice. Nkx2.2 cells were observed in the proximity of GFP<sup>+</sup> cells in the *Sema3F* group (Fig 6I). An increase in Nkx2.2<sup>+</sup> Ki67<sup>+</sup> cells was also detected, although it was not statistically significant due to an outlier in the GFP group (Grubb's test) (Fig 6K–P, Q). Yet, the proportion of Nkx2.2 cells that was expressing Ki67 were similar between the two groups (Fig 6R). These results suggest that *Sema3F* lesions recruit more OPCs, rather than significantly modifying their proliferation rate.

We also investigated whether oligodendroglial apoptosis is modified in *Sema3F* mice. Co-labeling for Olig2 (marker of OPCs and oligodendrocytes) and apoptosis marker-cleaved caspase 3 revealed low numbers of apoptotic cells in both GFP and *Sema3F* mice lesion/perilesion that were Olig2<sup>−</sup> (Fig 6S–Y). Thus, the presence of *Sema3F*-expressing blood-derived cells does not affect oligodendroglial apoptosis.

#### Increased oligodendrogenesis and remyelination in *Sema3F* mice

New oligodendrocytes in LPC lesions appear during the second week post-LPC (Fig 6A). Immunolabelings for APC/CC1<sup>+</sup> cells (oligodendrocytes) in the lesions of GFP and *Sema3F* mice at 7 and 10 dpl showed increased numbers of these cells in *Sema3F* mice at both time points (Fig 7A–C). Thus, increased OPC recruitment in *Sema3F* mice is followed by accelerated generation of new oligodendrocytes.

We then analyzed whether accelerated oligodendrogenesis also accelerates myelin repair. We used transmission electron microscopy (TEM) to quantify axons without myelin and those surrounded by thin myelin sheaths in the lesions at the onset of remyelination (14 dpl). While at this early time point demyelinated axons were predominant in both groups, the proportion of axons

surrounded by thin myelin sheaths was higher in Sema3F mice ( $2.12 \pm 0.73\%$  in GFP vs.  $13.83 \pm 3.39\%$  in Sema3F mice) (Fig 7D–G). The axons undergoing remyelination were frequently seen in the vicinity of macrophages (Fig 7H). Thus, Sema3F mice show a faster onset of remyelination.

Therefore, recruitment of Sema3F-expressing blood-derived macrophages to focal demyelinating lesions increases OPC repopulation, which accelerates oligodendrogenesis and remyelination.

### Discussion

Here, we have described a clinically relevant paradigm for targeting Sema3F to demyelinating lesions. Using transplantation of genetically modified HSCs, we showed that Sema3F-carrying blood-derived macrophages target areas of demyelination very quickly after demyelination, which results in increased OPC recruitment and accelerated remyelination. Increasing OPC recruitment and

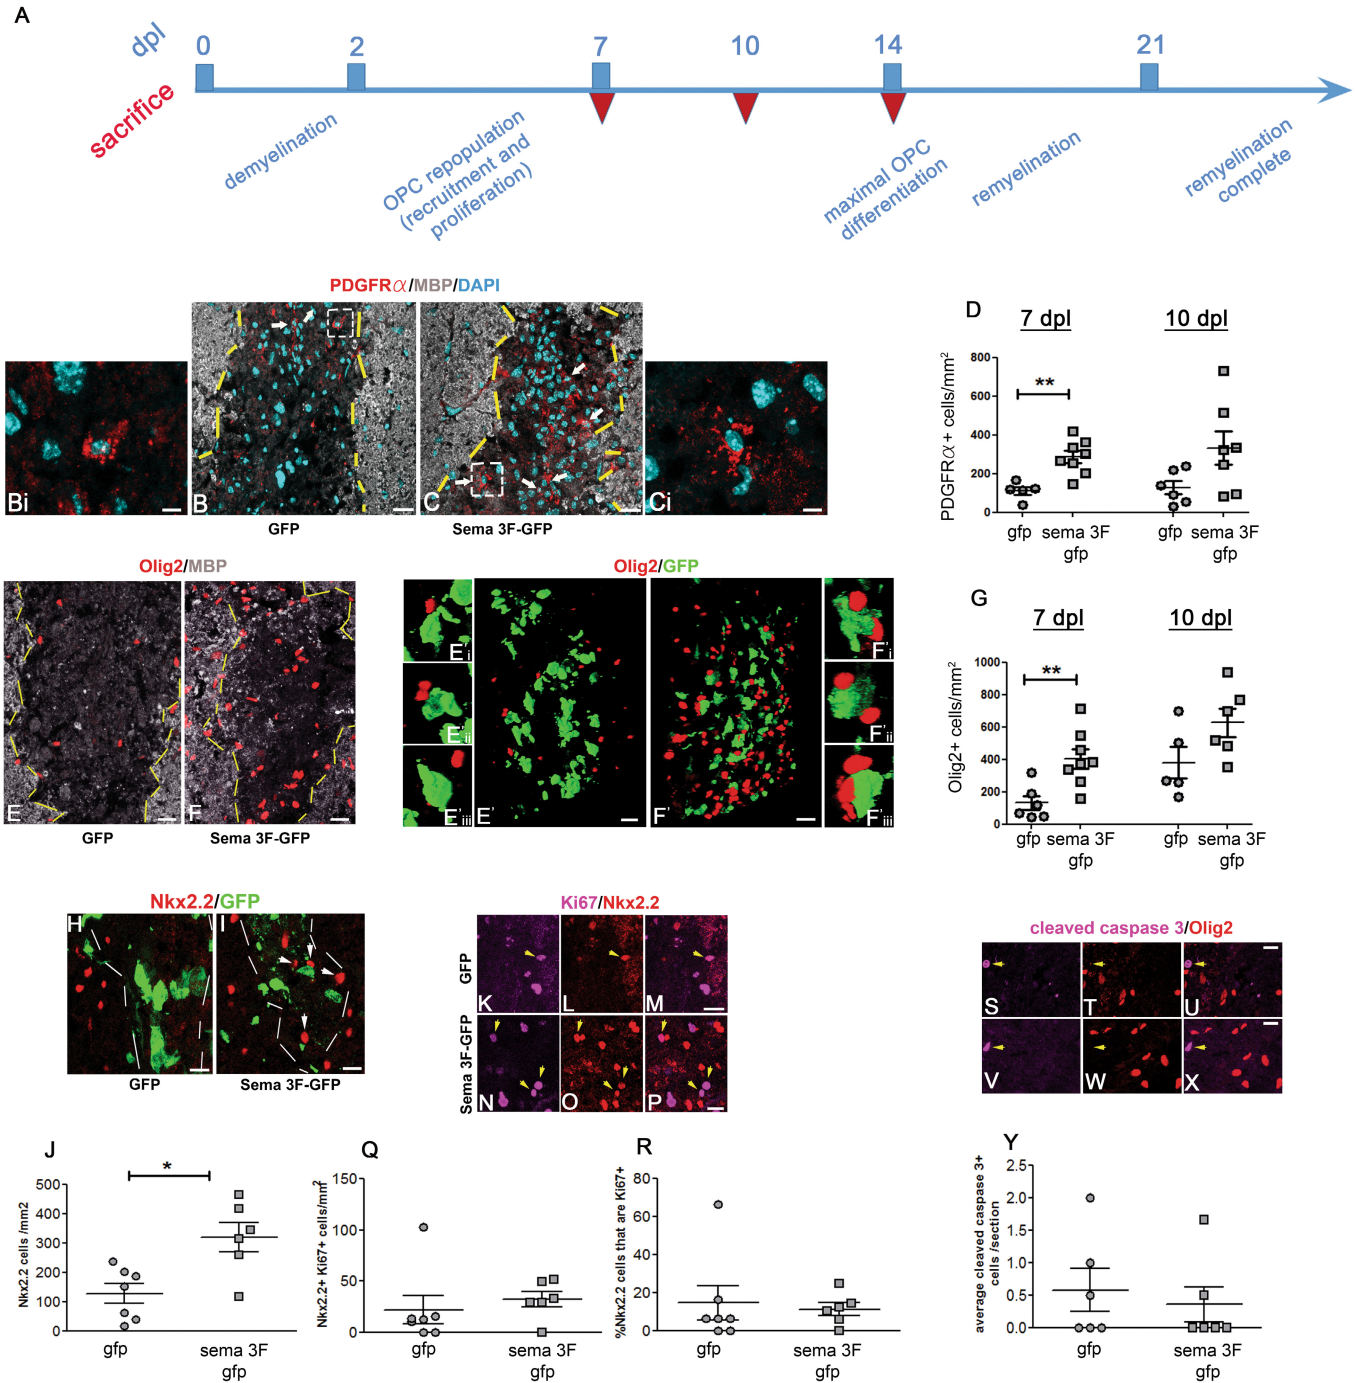

Figure 6.

Source data are available online for this figure.

accelerating remyelination are likely to benefit patients with MS for several reasons:

1. Acute inflammation in demyelinating lesions is beneficial and even necessary for successful myelin repair (Foote & Blake-more, 2005; Setzu *et al*, 2006). This means that quick recruitment of OPCs to areas of demyelination before the complete resolution of inflammation will enhance repair by these cells.
2. With time, axons undergo changes that may render them refractory to remyelination (Charles *et al*, 2002), which means that the more quickly the OPCs interact with the demyelinated axons the more likely is that remyelination will take place.
3. Within the (likely short) window of time when axonal pathology is still reversible, remyelination protects axons from degeneration (Kornek *et al*, 2000).
4. As previously shown, most OPCs in early MS lesions undergo differentiation and very few proliferate (Moll *et al*, 2013; Tepavčević *et al*, 2014; Wegener *et al*, 2015), which suggests that repeated rounds of demyelination observed in MS (Prineas *et al*, 1993; Brown *et al*, 2014) may exhaust the OPC pool and lead to remyelination failure (Tepavčević *et al*, 2014). Thus, replenishing the OPC pool during demyelination should benefit remyelination and enhance axonal protection in long term, thus potentially preventing/significantly delaying lesion chronicity and the development of permanent neurological deficit.

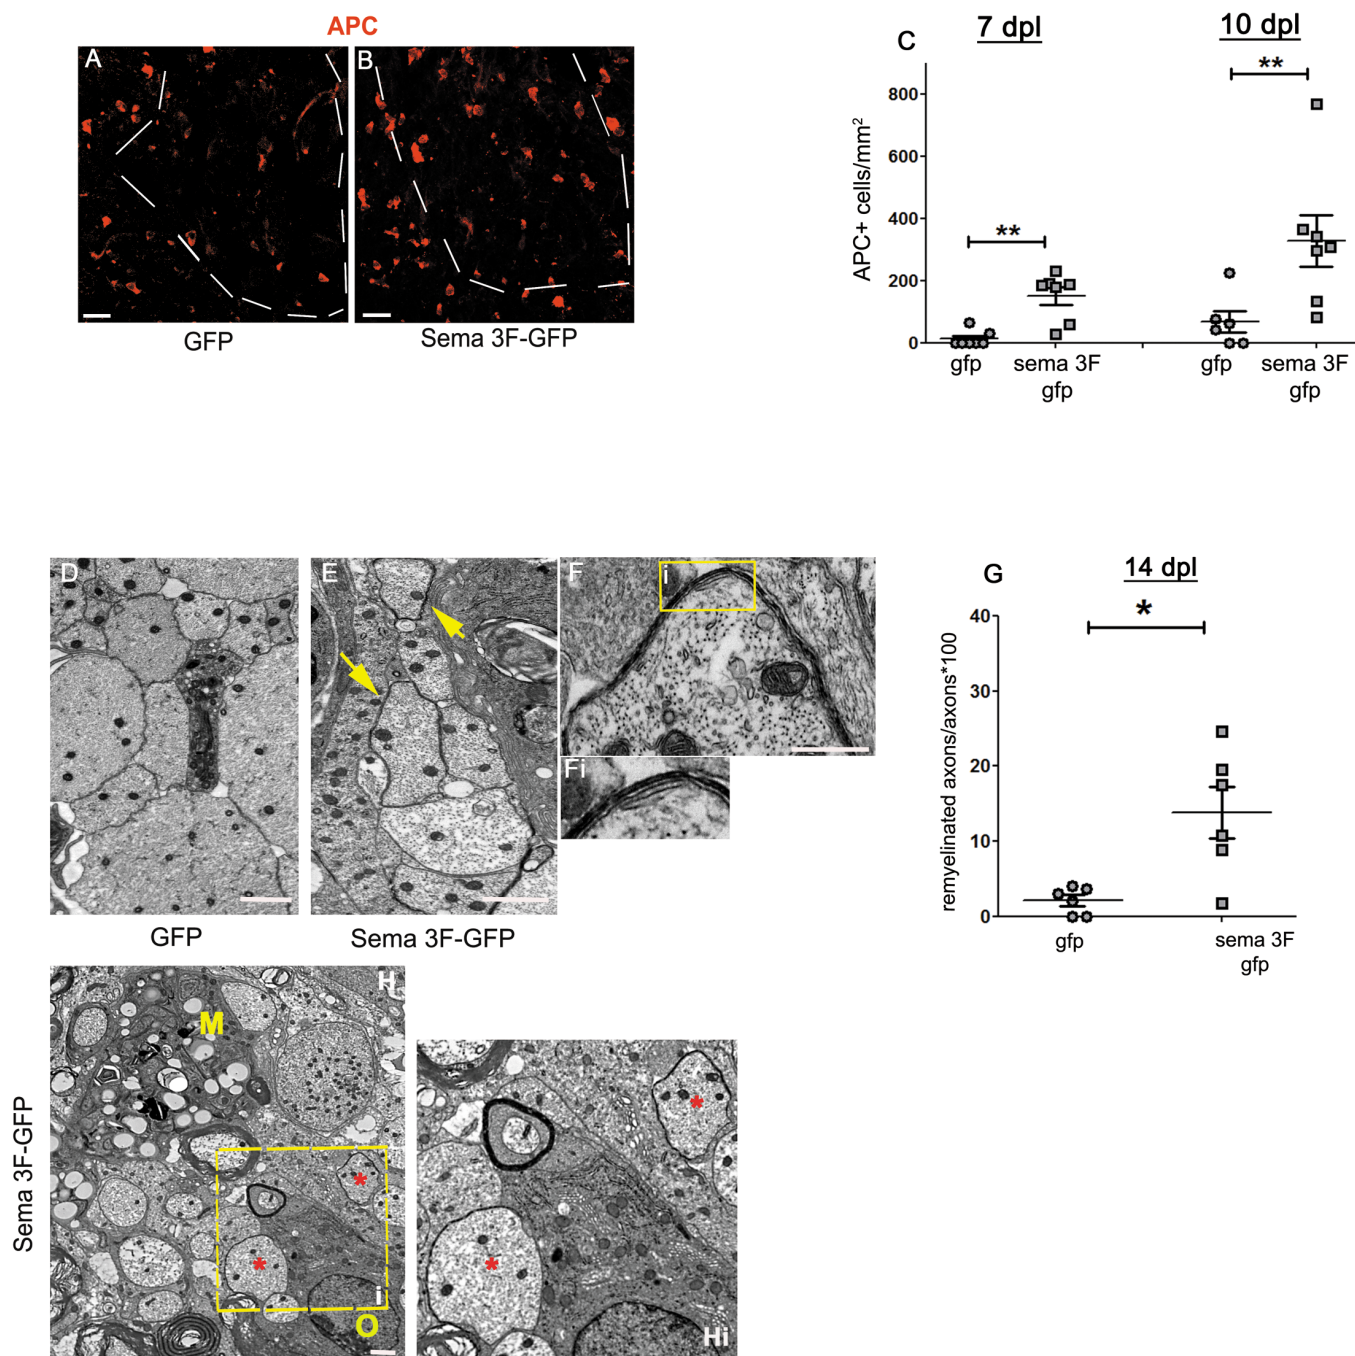

We used a lyssolecithin model to investigate whether OPC recruitment and remyelination can be enhanced by targeting *Sema3F* expression to demyelinating lesions via blood-born macrophages. The advantage of this model of acute demyelination induced by focal injection of membrane/myelin toxin lyssolecithin is that the induction of demyelination is largely independent of blood cells. This allowed us to study the effect of *Sema3F* overexpression in monocytes/macrophages on myelin repair without confounding effects on the extent of demyelination. While it would have been interesting to confirm our results in a model of diffuse demyelination (cuprizone intoxication), or autoimmune CNS inflammation (experimental autoimmune encephalomyelitis, EAE), the severity and high mortality risk in these models, incompatible with preconditioning protocols, precluded us from performing these experiments.

Because of the nature of the lyssolecithin model (with extensive myeloid infiltration and scarce presence of other immune cell types), the absolute majority of the infiltrating cells observed in our experiments were macrophages. The presence of *Sema3F*-expressing macrophages in the lesions did not affect the overall inflammatory status of the lesions as total numbers of macrophages, T cells, B cells, and microglia remained unchanged. It did not affect apoptosis in the lesioned tissue either.

The numbers of transgene-carrying cells decreased with time in the lesion and perilesional areas, which could be explained by the fact that immune cells infiltrating CNS have been reported to eventually undergo apoptosis (Pender *et al*, 1991), or because these cells simply leave via defined lymphatic channels (Tavares & Louveau, 2021). Interestingly, we did observe the persistence of some GFP<sup>+</sup> cells in the lesions and perilesional tissue at 60 dpl, which is consistent with the reports that busulfan preconditioning increases CNS engraftment of blood myeloid cells (Capotondo *et al*, 2012; Sailor *et al*, 2022).

Thus, given that neither inflammatory status of the lesion nor OPC survival were affected in *Sema3F* chimeras and that Nrp2 (*Sema3F* receptor) function-blocking antibody abrogated OPC migration in response to *Sema3F*-transduced HSC supernatant, we conclude that increased OPC recruitment in *Sema3F* chimeras is mediated by the interaction of blood cell-secreted *Sema3F* and Nrp2 expressed on OPCs.

Progression in MS tends to start in the early fifth decade of life (middle-age) (Confavreux & Vukusic, 2006). Importantly, in animal models, the efficiency of both OPC recruitment and remyelination decreases with age (Sim *et al*, 2002), which is already evident in middle-aged mice (9–12 months old). We investigated whether Nrp2 expression in OPCs diminishes with age, thus decreasing their responsiveness to *Sema3F*. Interestingly, we found that Nrp2 expression on OPCs is maintained in middle-aged mice, but the number of *Sema3F*-expressing cells in lesions is significantly lower in middle-aged and old animals. This suggests that OPC recruitment in older animals may be impaired, at least in part, due to decreased expression of *Sema3F* in lesions rather than OPC unresponsiveness to this molecule. Importantly, we showed that OPCs isolated from middle-aged animals efficiently migrate in response to both recombinant *Sema3F* and the supernatant from *Sema3F*-transduced HSCs. While

we do think that overexpressing Sema3F in MS lesions as early as possible (young patients with relapsing–remitting disease) would be the most optimal in stimulating remyelination to prevent neurodegeneration, conserved OPC responses to Sema3F in middle-aged mice suggest that such therapy may also be beneficial in early stages of progressive disease (most frequently occurring in middle-age individuals) to limit further axonal loss by enhancing remyelination of expanding lesions.

OPC repopulation of the lesions was enhanced in Sema3F chimeras at 7 dpl. Even though such repopulation is dependent on both OPC recruitment and proliferation, we think that Sema3F predominantly increased the recruitment because of the following:

1. As we showed previously (Piaton *et al*, 2011) and in this article, *in vitro* exposure of adult OPCs to Sema3F increases OPC migration, but has little effect on proliferation.
2. The proportion of OPCs undergoing proliferation was similar in control and Sema3F chimeras at 7 dpl (proliferation peak).

Most importantly, increased numbers of OPCs during recruitment phase, achieved using hematopoietic cell gene therapy, were associated with accelerated myelin repair. We think these findings have important implications for the development of remyelination-promoting therapies in MS. In addition to promoting OPC recruitment which, if performed during early phases of the disease, could promote remyelination and neuroprotection thus preventing disease chronicity, this paradigm could also be used to overexpress neurotrophic factors and antioxidant molecules, potentially beneficial for progressive MS (Mahad *et al*, 2015).

Developing strategies to prevent, as well as treat progressive MS is an unmet therapeutic need. We believe that successful remyelination-promoting strategies in relapsing–remitting MS should greatly reduce the likelihood of progressive disease, and efficient targeting of repair-promoting molecules appears crucial to achieving this. The strategy we are proposing relies on blood-derived macrophage infiltration in CNS lesions that are undergoing activity, both in RRMS and early progressive MS, while axons are still viable. In this manner, OPC recruitment would be stimulated prior to the formation of glial scar, to promote remyelination thus preventing/reducing axonal loss. Interestingly, the treatment with busulfan, the drug used as a preconditioning treatment for HSCT, enhances CNS engraftment of blood monocytes derived from grafted HSCs, even in the absence of blood–brain barrier breakdown (Capotondo *et al*, 2012; Sailor *et al*, 2022). This explains the benefits of genetically modified HSCT described in patients with leukodystrophies, and suggests that: (i) MS lesions in the progressive phase (with no breakdown of blood–brain barrier) may also be targeted by transgene-carrying blood monocytes to enhance remyelination and (ii) Blood cells that entered CNS during one attack may become established there, thus be available for another demyelinating episode. In addition, as mentioned above, macrophage-mediated delivery of neurotrophic factors to the CNS may be beneficial in preventing/reducing global CNS neurodegeneration observed in progressive disease.

We have used transplantation of HSCs as means of obtaining transgene-carrying monocytes/macrophages. Autologous HSC transplantation (aHSCT) has been used to stabilize the disease in a defined population of patients with RRMS, with little or no benefits

observed in progressive disease (Sharrack *et al*, 2020), likely because suppressing inflammation is not sufficient to promote remyelination at this stage. Theoretically, combining genetic modification of HSCs with autologous transplantation in clinics might potentially both regulate inflammation and promote regeneration, thus extending the benefits of aHSCT to a wider subset of eligible patients. However, it must be taken into account that aHSCT is associated with significant side effects, in part due to preconditioning regimens, and is therefore recommended only for patients with very aggressive inflammatory disease and resistant to conventional therapies (Sharrack *et al*, 2020). It is important to highlight that application of genetically modified macrophages to increase remyelination could also be achieved using alternative strategies. One of these, potentially applicable to a larger population of patients (in which aHSCT is not recommended), may be to systemically deliver engineered monocytes amplified from autologous progenitor cells, as previously described (Li *et al*, 2015), given that demyelinating MS lesions are always associated with the presence of myeloid lineage cells (Lassmann, 2018). Future work should test this strategy, which does not require preconditioning, first in rodent models such as the lysolecithin injection, cuprizone intoxication, and EAE, and then, if benefits are confirmed, in marmoset EAE, considered as the most suitable preclinical model of MS (Kap *et al*, 2016; Donadieu *et al*, 2021). Moreover, it may be possible to restrict the expression of the transgene using specific promoters, so that the expression becomes upregulated specifically when the cell is performing phagocytosis (myelin debris), and thus reduce potential side effects in non-lesioned tissue, even though this may not be crucial if one aims to overexpress neurotrophins/antioxidants.

In conclusion, we provide a proof of concept that targeted molecular delivery by genetically modified blood-derived macrophages increases OPC recruitment and accelerates remyelination. Although further data are required to clearly define the suitability of this strategy for specific patient subpopulations, these results and recent advances in gene therapy for human CNS diseases (Piguet *et al*, 2017) suggest our approach as a potentially useful therapeutic strategy to prevent/improve disability in MS.

## Materials and Methods

### Mice

Five- to 7-week-old female and 9-week-old male C57/BL6 mice were purchased from Janvier (France). All animal manipulations were performed after a period of adaptation to the animal house of at least 1 week. Aged mice (9 month-, 12 month-, and 18 month-old) were aged in the facility. The experiments were performed according to the European Union regulations and approved by the ethical committee for animal use (approval number 18471). Mice were housed under standard conditions and given *ad libitum* access to dry food and water. The design of animal experiments was inspired by ARRIVE guidelines.

### Isolation and culture of mouse hematopoietic stem/progenitor cells (HSCs)

Six- to 8-week-old female mice were sacrificed by cervical dislocation. Tibias and femurs were dissected and bone marrow flushed

using a syringe. Differentiated white blood cells were then removed using Direct Lineage Cell Depletion kit (Miltenyi Biotec). The resulting mixture of hematopoietic stem and progenitor cells was then kept in culture in IMDM (Sigma) supplemented with FBS (Sigma), and mSCF, hIL6, and mL3 (all from Peprotech) in six-well plates for 16–24 h at 37°C.

### Lentiviral vector generation

DNA sequence-encoding green fluorescent protein (GFP) alone or GFP and human semaphorin 3F (Kusy *et al*, 2003), separated by a self-cleaving T2A sequence, were synthesized and inserted into the self-inactivated vector (SIN) backbone containing the WPRE element and the murine ubiquitous phosphoglycerate kinase 1 promoter (PGK). Lentiviral vectors were generated at the Molecular Biology and vector production platform, MIRCEN, François Jacob Institute of Biology, CEA (Fontenay-aux-Roses, France), as described previously (Cresto *et al*, 2020). The SIN vectors were pseudotyped with VSVg glycoprotein G. Viral particles were produced in human embryonic kidney (HEK)-293 T cells by a four-plasmid transient transfection system. The supernatant was collected 48 h later and filtered, and the particle content of the viral batches was determined by ELISA for the p24 antigen (Gentaur, Paris, France). High-titer stocks were obtained by ultracentrifugation. The pellet was re-suspended in 1% BSA in PBS, frozen, and stored at –80°C.

### Transduction of HEK cells and supernatant collection for migration assays

HEK 293 T cells were grown in DMEM-Glutamax™ medium (Gibco) supplemented with 10% fetal calf serum at 37°C and 5% CO<sub>2</sub>. Eighty percent confluent cells were transduced with PGK-GFP-T2A-Sema3F or PGK-GFP lentiviral vectors at a multiplicity of infection (MOI) of 10–20 for 24 h. Medium was replaced and transduced cells were grown for 3–5 days. Supernatant was collected and stored at –80°C.

### Lentiviral transduction of HSCs

Lentiviral transductions were performed in IMDM medium supplemented with FBS, mSCF, hIL6, mL3, and protamine sulfate (Sigma). PGK-GFP and PGK-GFP-T2A-semaphorin 3F vectors were applied at an MOI of 50 and cells were incubated at 37°C for 24 h. Control cells were incubated without lentiviral vectors. For supernatant collection, the medium was replaced and transduced cells were grown for 3–5 days. The supernatant was collected and stored at –80°C.

### In vitro expansion, transduction efficiency, and viability test

Transduced cells were collected, washed, counted, and resuspended in IMDM medium with FBS (Sigma), and mSCF, hIL6, and mL3 (all from Peprotech) in six-well plates at an initial density of 10<sup>5</sup> cells/ml. Every other day, fresh medium was added to the well, and cells were passaged to new wells as needed. After 5 days of culture, cells were collected, washed, counted, and resuspended in PBS. GFP expression (endogenous fluorescence) and viability (propidium iodide (PI) and Viability 405/520 Fixable Dye (Miltenyi Biotec)

staining) were investigated using flow cytometry (LSR Fortessa, Benton Dickinson).

### Colony-forming unit assay

Transduced cells were collected, washed, and resuspended in MethoCult™ GF M3434 medium (Stemcell) at a density of 1,000 cells/ml and grown in six-well plates (1,000 cells/well) for 10–11 days. Numbers of erythroid, myeloid, and GFP<sup>+</sup> colonies were counted and compared between the conditions.

### Western blot

Following transduction and 5-day expansion, cells were pelleted by centrifugation, and the supernatants were collected. Cell pellets were lysed in a lysis buffer containing protease inhibitor cocktail (Sigma or Thermofisher). Both the protein extracts from cell pellets and the supernatants from cultured cells were subjected to protein quantification using BCA Protein Assay kit (Thermofisher). Samples were boiled at 95°C for 5 min, size separated by SDS-PAGE in 4–20% Criterion TGX Precast gels, and transferred using Trans-Blot Turbo Midi Nitrocellulose Transfer Packs (Bio-Rad). Membranes were blocked with 5% skim milk in Tris-buffered saline/0.1% Tween-20 (TBS-T) for 1 h at RT. Primary antibodies (Goat anti-GFP biotin conjugated, Vector Labs; sheep polyclonal anti-human-Sema3F antibody, R&D systems; and mouse anti-GADPH, Abcam) were diluted in the blocking buffer, and the membranes were incubated with antibody solution under gentle shaking overnight at 4°C. Following three washes in TBS/Tween-20 0.1%, Biotin-conjugated polyclonal anti-sheep IgG (Vector Labs) in the case of anti-Sema3F antibody was applied for 1 h at RT. HRP-conjugated streptavidin (Vector Labs) was applied for 1 h. For anti-GADPH labeling, HRP-conjugated Donkey anti-Mouse IgG (Thermofisher) was applied. Bands were visualized using an enhanced chemiluminescence detection kit (BioRad). Images were acquired using a Fusion FX imaging chamber (Vilber).

### In vitro migration assay

Purified OPCs, isolated using FACS from the brains of 2-month-old (young) and 9-month-old (middle-aged) PDGFR $\alpha$ -GFP mice, as previously described (Piaton *et al*, 2011; Tepavčević *et al*, 2014), were resuspended in a modified Bottenstein–Sato (BS) medium and plated at the upper face of the porous membrane of the transwell chamber (Corning Costar Co, USA) positioned over the well within the 24-well plate (Corning) at a density of 10,000 cells per membrane. Five hundred microliters containing a 1:1 mixture of the BS medium and supernatant from non-transduced (NT)-, PGK-GFP-transduced, or PGK-GFP-T2A-Sema3F-transduced HSC or HEK cells were added to the well. Anti-Nrp2 function-blocking antibody (AF2215, R&D Systems) was applied at a concentration of 10  $\mu$ g/ml. Following a 24-h incubation period, the cells present at the upper surface of the membrane were scraped off and the membrane fixed using 4% paraformaldehyde (PFA) solution. Nuclei were labeled with Hoechst and cells present on the lower surface of the membrane counted. The assays were performed as duplicates or triplicates. The statistical analyses were performed on replicates normalized to the average number of migrated control cells from

the same experiment from three to five independent experiments and presented as fold change in the number of cells crossing the membrane insert relative to the control (NT) for each independent experiment.

### Preconditioning and cell transplantation

Recipient mice (10- to 12-week-old males) were injected (intraperitoneally) with cyclophosphamide (Sigma) at 200 mg/kg for two consecutive days (total of 400 mg/kg), and then with busulfan (Sigma) at 25 mg/kg for four consecutive days (total of 100 mg/kg). This procedure inhibits the proliferation of recipient cells and enhances transplanted cell integration.

The day following the last injection of busulfan, transduced cells were collected, washed, and resuspended in alphaMEM (Fisher Scientific) at a density of 3,000 cells/ $\mu$ l. Preconditioned mice were anesthetized with isoflurane, and 200  $\mu$ l of cell suspension (600,000 cells total) was injected retro-orbitally. Mice were randomly selected to receive GFP- or Sema3F-GFP-transduced cell preparation. Mice were treated with Baytril for 1 month following preconditioning and transplantation, and their weight was recorded weekly.

### Detection of blood chimerism for transplanted cells

The presence of donor cells was investigated in the blood of transplanted mice using qPCR for sex-determining region of the chromosome Y (SRY). Briefly, at 8 weeks post-transplantation, blood was isolated from transplanted mice by submandibular bleed, and gDNA was extracted. qPCR was performed using primers specific for actin (Sigma) and SRY (ThermoFisher). Quantification was performed using the  $2^{-\Delta\Delta C_t}$  algorithm.

### Detection and characterization of transduced cells in the blood of transplanted mice

To detect the presence of cells transduced with lentiviral vectors in the blood of transplanted mice, blood was isolated at 8 weeks following transplantation. Red blood cells were lysed using a Red Blood Cell Lysis Buffer (ThermoFisher), the cells were washed and the proportion of GFP<sup>+</sup> cells was investigated using flow cytometry.

To characterize transduced cells in the blood, labeling with antibodies specific for different hematopoietic lineages was performed: CD11b (BD Bioscience; monocyte marker), CD3 (BD Bioscience; T cell marker), and CD19 (Bd Bioscience; B cells marker). The viability was investigated using Viability 405/520 Fixable Dye (Life Technologies). All markers were applied at 1:10 dilution. Cells were analyzed using the cytometer LSR Fortessa (Benton Dickinson).

### Induction of demyelinating lesions

At 10 weeks post-HSC transplantation in chimeric mice, or in 2-month-old, 12-month-old, and 18-month-old control mice, demyelinating lesions were induced in the spinal cord by a stereotaxic injection of 0.5  $\mu$ l of 1% lysophosphatidylcholine (LPC, Sigma Aldrich) in sterile 0.9% NaCl solution. Chimeric mice were at least 20 weeks old at the time of lesion induction. Prior to the surgery, mice were anesthetized by intraperitoneal injection of ketamine (90 mg/kg)

and xylazine (20 mg/kg) cocktail. Two longitudinal incisions into longissimus dorsi at each side of the vertebral column were performed and the muscle tissue covering the column was removed. Animals were placed in a stereotaxic frame, the 13<sup>th</sup> thoracic vertebra fixed in between the bars designed for manipulations on mouse spinal cord (Stoelting, USA), and intravertebral space exposed by removing the connective tissue. An incision into dura mater was performed using a 30G needle and LPC was injected using a glass micropipette attached via a connector to Hamilton's syringe and mounted on a stereotaxic micromanipulator. The lesion site was marked with sterile charcoal. Following LPC injection, the muscle sheaths were sutured with 3/0 monocryl, and the skin incision closed with 4/0 silk.

### Perfusion and tissue processing

Mice were euthanized with Imalgene and perfused with a 4% PFA (Sigma) solution in phosphate-buffered saline (PBS; pH 7.4) for immunohistochemical (IHC) analysis or 4% glutaraldehyde (Electron Microscopy Sciences) solution supplemented with calcium chloride in 0.1 M phosphate buffer (PB) for transmission electron microscopy (TEM). For IHC analysis, spinal cords were re-equilibrated in 15% sucrose solution and frozen in 15% sucrose–7% gelatine solution in PBS. Twelve-micron coronal sections were cut using cryostat (Leica). For EM analyses, spinal cords were post-fixed overnight, washed in 0.1 M PB, and cut into four 1-mm-thick transverse blocks surrounding the injection area. The next day, the tissue was post-fixed in 1% osmium for 2 h, rinsed, dehydrated, and embedded in Epon-812 resin (EMS).

### Antibodies and immunohistochemistry

Primary antibodies used for immunohistochemistry were as follows: Millipore antibodies: chicken anti-MBP (AB9348, 1:200), mouse anti-Olig2 (MABN50; 1:200), rabbit anti-GFP (AB3080, 1:500), and mouse anti-MOG (MAB5680, 1:200); BD Biosciences antibodies: rat anti-PDGFR $\alpha$  (558774, 1:200) and rat anti-CD45R/B220 (557390, 1:200); rabbit anti-cleaved caspase 3 (9661, Cell Signaling, 1:400); mouse anti-APC (OP80, Calbiochem; 1:200); guinea pig anti-Iba1 (Synaptic Systems; 234004, 1:300); Serotec antibodies: rat anti-CD68 (MCA19575, 1:200), rat anti-CD11b (MCA711; 1:200), and rat anti-CD3 (MCA1477, 1:50); rabbit anti-Iba1 (Wako; 019–19741; 1:250); rat anti-Sema3F (R&D Systems, MAB3237, 1:50); and rabbit anti-P2Y12 (Anaspec, AS-55043A, 1:200). Secondary antibodies used were Alexa-conjugated goat antibodies (Invitrogen) and were used at 1:1,000.

Sections were air-dried for 1 h and re-hydrated in TBS. For all stainings, except for PDGFR $\alpha$ , antigen retrieval was performed by heating the sections in a low pH retrieval buffer (Vector Labs) at high power using a microwave for 45 s. After washing in TBS, slides were incubated in absolute ethanol solution for 15 min at  $-20^{\circ}\text{C}$ . After washing, blocking buffer (TBS, 5% NGS, 1% BSA, 0.1% Triton, or BlockAid solution (ThermoFisher)) was applied for 30 min, followed by primary antibody incubation overnight at  $4^{\circ}\text{C}$ . In the case of PDGFR $\alpha$ , Triton was not used for overnight incubation. Sections were washed, and secondary antibodies were applied for 1 h. After washing, nuclei were counterstained with DAPI. Slides were mounted in Fluoromount-G (ThermoFisher Scientific).

### Cell type and Sema3F expression quantification in demyelinating lesions

Images were collected from 2 to 3 consecutive sections 144  $\mu\text{m}$  apart containing the central part of the demyelinating lesion using a TCS STED CW SP8 super-resolution microscope (Leica) and imported into NIH ImageJ software. The investigator in charge of imaging acquired the images and named them using the mouse unique identifier (without age or condition). Quantification was performed blinded, the identity/age/condition of each mouse was revealed after quantification. The area lacking MBP staining within the dorsal funiculus was delimited on a corresponding channel and imported onto the other channels to regionally restrict the analyses. For each image, the area of demyelination was measured and cells positive for the marker(s) of interest were counted. Results are presented as the total number of positive cells per lesion area measured or the percentage of the total.

### Quantification of remyelination

Ultrathin sections were cut by one investigator and imaged and quantified by different investigators. The investigator who cut the ultrathin sections placed the grids in the grid box in random order. The investigator in charge of imaging acquired the images and named them using the grid-box well identifier. Serial images were taken throughout the lesion to cover the demyelinated area using a transmission electron microscope JEOL JEM 1400 Plus (JEOL) connected to a digital camera (sCMOS), and imported into ImageJ. Remyelinated and demyelinated axons were counted. After quantification, the identity of the grid was revealed. Results are presented as the percentage of the total axons counted.

### RNA extraction and microarray analyses

For each condition, we used four independent FACS samples to provide four biological replicates, as previously described (Moyon *et al.*, 2015). Total RNA was extracted using NucleoSpin RNA XS kit (Macherey-Nagel). The quantity and quality of RNA extractions were analyzed using Agilent RNA 6000 Pico kit (Agilent). Labeled RNAs (Liq Kit, Agilent) were then hybridized onto Agilent whole-mouse genome microarray chips. Data were normalized and analyzed using the R statistical open tool (R Manuals; RRID:OMICS\_01764). We used a Student's *t*-test and Benjamini–Hochberg test to identify the differentially expressed genes between two conditions (cutoffs:  $P < 0.001$  and  $q < 0.01$ , respectively). The datasets used in this study are available in the following databases: NCBI GEO (Gene Expression Omnibus; RRID:nif-0000-00142); accession number: GSE48872 (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE48872>).

### RNA sequencing

For control and lesion, oligodendroglial-enriched tissues (isolated following Percoll gradient cell separation from enzymatically dissociated spinal cord tissue) (Moyon *et al.*, 2021), approximately 10 ng of total RNA per sample, were used for library construction with the Ultra-Low-RNA-seq RNA Sample Prep Kit (Illumina) and sequenced using the Illumina HiSeq 4000 instrument according to the

### The paper explained

#### Problem

Multiple sclerosis (MS) is a chronic demyelinating disease of the central nervous system (CNS) that represents the leading cause of non-traumatic neurological disability in young adults. The disease is characterized by disseminated inflammatory lesions in which myelin loss predisposes axons to degeneration. The process of myelin regeneration (remyelination) is neuroprotective and represents a potential therapeutic target to prevent the development of permanent disability. Remyelination can be increased in animal models by overexpressing semaphorin 3F (Sema3F) that acts as an attractant for oligodendrocyte progenitor cells (OPCs; the remyelinating cells of the CNS) using direct lentiviral vector injections in the lesions. However, efficient targeting of pro-remyelinating molecules to disseminated demyelinating lesions in clinical settings is a major challenge.

#### Results

We have demonstrated that genetic modification of hematopoietic stem cells to overexpress Sema3F leads to targeted delivery of the transgene to demyelinating lesions by lesion-infiltrating macrophages, which increases OPC recruitment, and accelerates generation of new oligodendrocytes and remyelination.

#### Impact

Genetic manipulation of the blood cells is a clinically relevant strategy successfully applied in various human leukodystrophies (genetic diseases of myelin) to carry the missing protein to the brain. Our findings suggest this therapy could be also employed in patients with MS to stimulate remyelination, as well as to overexpress neuroprotective factors to prevent neurodegeneration.

manufacturer's instructions for 100 bp paired-end read runs. High-quality reads were aligned to the mouse reference genome (mm10), RefSeq exons, splicing junctions, and contamination databases (ribosome and mitochondria sequences) using the Burrows–Wheeler Aligner (BWA) algorithm. The read count for each RefSeq transcript was extracted using uniquely aligned reads to exon and splice-junction regions. The raw read counts were input into DESeq2 v1.2.5 81, for normalizing the signal for each transcript and to ascertain differential gene expression with associated *P*-values. We used a cut-off of *P*-value  $< 0.01$  and *Q*-value  $< 0.05$  to identify differentially expressed genes. The datasets used in this study are available in the following databases: NCBI GEO (Gene Expression Omnibus; RRID:nif-0000-00142); accession number: GSE122446 (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE122446>).

### Statistics

All data are expressed as mean  $\pm$  SEM. Statistical analyses were carried out using Prism software (GraphPad Software), with *P*-values  $< 0.05$  considered significant. First, data distribution was verified using Prism (D'Agostino and Pearson Normality test), and subsequently, the appropriate parametric versus non-parametric test was chosen. For IHC and EM analyses, as the normality test indicated, data were analyzed using non-parametric statistics, with Kruskal–Wallis test to compare three or more groups, followed by Tukey's multiple-comparison *post hoc* test. Depending on the results of the normality test, differences between two groups were analyzed using Mann–Whitney test or unpaired Student's *t*-test (two tailed).

Numbers of replicates and *P*-values relevant to specific data are presented in the figure legends.

## Data availability

Data are available in the “Source Data” file and repositories cited in “Methods” (Moyon *et al*, 2015, 2021) with accession numbers: GSE48872 (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE48872>) and GSE122446 (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE122446>). Any additional data are available upon reasonable request.
