10 Abstract

11 Paleoclimatic evolution of the last 140 ka (Marine Isotopic Stages MIS 1 to MIS 5) in the South
12 Bay of Biscay has been studied by considering changes of microfossils from sediment samples of
13 deep core PP10-17. This core was retrieved at 2882 meters water depth (mwd) in the Landas
14 Plateau and is formed by 1792 cm of clay-silt continuously deposited sediment. A subset of 114
15 samples has been used for this study, yielding more than 62 thousands of specimens of
16 foraminifers (181 benthic species, BF) and ostracods (70 spp.). Benthic response is based on
17 main foraminifer and ostracod species by considering the oxic character and other ecological
18 features of the assemblages. Detailed quantification of microfossils (planktonic and benthic
19 foraminifers, ostracods) besides sedimentological and geochemical data (granulometry, magnetic
20 susceptibility) allow us to characterize many of the climatic events registered in this core. Based
21 on a solid chronostratigraphy by correlation with reference cores MD95-2042 (estimation of SST,
22 sea surface T) and GICC05modelext-NGRIP 1,2 (ice core, atmospheric signal), detailed
23 responses of benthics to cooling/warming, oxygen-content and productivity cycles have been
24 proposed. MIS 5 was characterized by oscillations of the oceanicity index (OI; 60-90); this index was
25 higher (90-100) and stable through the MIS 4-MIS 3 intervals. We found BF species indicators of
26 different climatic-related events. Thus, MIS 5 interglacials are evidenced by *Bulimina gibba* and *B.*
27 *aculeata* while the stadials MIS 5b, d are shown by the occurrence of *Melonis pompilioides*. The
28 Heinrich events H, when there were strong iceberg discharges into the N Atlantic Ocean, are
29 indicated by *Globobulimina affinis*, particularly during the MIS 4 to MIS 2 interval. The beginning of
30 MIS 4 is indicated by the entrance of new species of BF and a shift of *Cassidulina laevigata*. *Krithe*
31 spp. and *C. laevigata* are good indicators of cold intervals of the LGM (Last Glacial Maximum, 19-
32 23 ka) when decreased the OI. Minor cooling periods as YD (Younger Dryas, around 12-13 ka)
33 are shown as well by a shift of *M. pompilioides*, similar to that of the MIS 5d stadial. The Holocene
34 (11.5 ka to present) is marked by the increase of the oceanicity index, disappearance of cold-water

35 indicators and the occurrence of *Uvigerina peregrina*. A shallow infaunal microhabitat of benthics
36 foraminifers (*Cibicides*, *Cassidulina*, *Uvigerina*) and ostracods (*Krithe*, *Argilloecia*) was related with
37 favorable bottom conditions, with oxic to slightly suboxic and relatively ventilated bottoms (high
38 diversity and equitability of assemblages) reflecting active AMOC during many D/O interstadials.
39 The opposite conditions were established for deep infaunal BF (*Bulimina*, *Globobulimina*) where
40 the strong dysoxic bottom conditions were indicative of low ventilation produced by reduced or
41 shutdown of the AMOC, mostly during Heinrich stadials.

42 Key-words: Paleoclimatology, foraminifers, ostracods, benthic response, MIS 1-MIS 5, Bay of
43 Biscay

44 **1. Introduction**

45
46 The relationship between paleoceanography and paleoclimatology has largely been established in
47 the comparative study of biological and bio-geochemical proxies evaluating the different
48 responses of the sea surface and the deep sea to the atmospheric fluctuations (e.g. Cronin, 2009
49 and references therein; Povea et al., 2016). Though imperfect, the deep-sea benthic foraminifera
50 oxygen isotope is the best stratigraphic reference to the study of glacial-interglacial changes
51 (Tzedakis et al., 2009).

52 Taking the Atlantic Ocean as a model, the rapid alternation of warm (interstadials) and cold
53 (stadials) intervals have been proposed as characteristic climatic oscillations during the last glacial
54 cycle (Lisiecki and Raymo, 2005), and climatic connections with the Atlantic have been described
55 for the Mediterranean (Cacho et al., 1999; Moreno et al., 2007). Though the cold Heinrich stadials
56 (HS) and warm Dansgaard-Oeschger (D/O) events are reasonably known in particular to the MIS
57 3 (Sierro et al., 2005; Naughton et al., 2009, 2016), the details about thermal trends are yet in
58 discussion (Long and Stoy, 2013). Rapid climate variability in N Atlantic represented by the
59 alternation of cold and warm phases has been linked to significant changes in the strength of the
60 AMOC (Atlantic Meridional Overturning Circulation), but particular behavior during D/O
61 interstadials inside the Heinrich events were associated with overturning circulation rapidly
62 transmitted across the Atlantic (Gottschalk et al., 2015).

63 On the other hand, the benthic response to these rapid climatic changes has been evaluated in
64 several works for the deep N Atlantic (Baas et al., 1998; Cronin et al., 1999, 2000; Rasmussen et
65 al., 2002; Yasuhara et al., 2008; Hoogakker et al., 2015, 2016; Grunert et al., 2015), and in the
66 Bay of Biscay mostly relative to shelf environments during the Marine Isotope Stage MIS 3 to
67 Holocene (Pascual et al., 2008; García et al., 2013; Martínez-García et al., 2013, 2014, 2015).
68 Recent deep benthic foraminifer distribution is well known in the area of the Bay of Biscay (Caralp
69 et al., 1968; Pujos-Lamy, 1973, 1984). Deep benthic foraminifer distribution is influenced by

70 organic carbon flux, bottom currents and grain size, oxygen content and carbonate saturation of
71 sediment (Mackensen et al., 1995; Jorissen et al., 2007). The relationship between opportunistic
72 benthic foraminifers and primary production and oxygen content was analysed in several transects
73 from the shelf to the bathyal Bay of Biscay by Fontanier et al. (2002, 2003, 2006) and Mojtahid et
74 al. (2010). These authors monitored changes in the benthic microhabitat responding to the trophic
75 conditions of the water-sediment interface following the TROX-model (TRopic conditions and
76 OXigen concentrations) of Jorissen et al. (1995).

77 Several aspects of the paleoceanography of the Bay of Biscay have been previously considered.
78 Zaragosi et al. (2001) considered surface and deep conditions in the Meriadzek Terrace. The Last
79 Glacial Maximum (LGM) was characterized by a gradual warming with at least two pulses of the
80 North Atlantic Drift (NAD) that finally lead to the collapse of Heinrich event H1.

81 Naughton et al. (2009, 2016) characterized the Heinrich events (H4 to H1) in NW Iberia comparing
82 marine and terrestrial records. The robust chronostratigraphic framework allowed the authors
83 revealing the complex nature of H1, describing detailed cooling/warming trends. Sanchez Goñi et
84 al. (2013) described the MIS 5a-4 transition in N Atlantic with three cold events (C20, C19, C18;
85 80-70 ka BP). The thermal gradient between sea surface temperatures (SST) and air temperature
86 (warm surface ocean in the W European marginal areas) resulted in increased input of humidity
87 that fed the continental ice sheets in the North Atlantic.

88 The aim of this study is to provide with new evidence of deep-sea benthic response to rapid
89 climate changes produced during the last glacial cycle, based on detailed new data of benthic
90 foraminifers and ostracods completed with sedimentary analyses in a bathyal settlement in the SE
91 Bay of Biscay.

92 93 *1.1. Environmental setting*

94
95 Surface circulation in the Bay of Biscay is characterized today by a general oceanic current formed
96 by anticyclonic ENACW (Eastern North Atlantic Central Water) (Koutsikopoulos and Le Cann,
97 1996) and proximally by the Iberian Poleward Current (IPC), with a strong seasonal component
98 counter-clock winter slope current (Durrieu de Madron et al. 1999; Fig. 1). In the southern area
99 surface water circulation is mainly induced by winds and water density variations produced by
100 freshwater runoff from French and Spanish rivers (Koutsikopoulos and Le Cann, 1996; Ferrer et
101 al., 2009), finally producing seasonal oscillations in salinity and nutrient discharges in surface
102 waters (Puillat et al. 2004). Inceptions of IPC current into the Bay of Biscay have been correlated
103 to negative NAO (North Atlantic Oscillation) phases (Decastro et al. 2011).

104 Main water masses in the Bay of Biscay are AABW (Antarctic Bottom Water; >3000 mwd),
105 NEADW (North East Atlantic Deep Water; 3000-1300 mwd), the high-saline MOW (Mediterranean

106 Outflow Water; 1300-700 mwd) and the ENACW (East North Atlantic Central Water; <700 mwd)
107 (van Aken 2000a,b, 2001). Core of this study is located in the lower NEADW.

109 **2. Material and methods**

110 *2.1. Core PP10-17*

111 Data for this work come from core PP10-17, of the SARGASS oceanographic cruise, retrieved in
112 2010 at 2880 mwd (43° 58.91 N - 03°14.05 W; Fig. 1) in the SW Landes Plateau. Core length is
113 1792 cm with a lithology of silty clay continuously deposited sediment. Sedimentology processing,
114 included granulometry and X-ray fluorescence element analyses at high resolution, has been
115 performed at the Bordeaux I University (for details see Brocheray et al., 2014).

116 Samples for microfossils have been processed at the University of the Basque Country
117 (UPV/EHU) following standard methodology. Sediment sample (1 cm max. resolution) was
118 washed and sieved (63 µm mesh) and dried. A second separation was made, sieving with 150 µm
119 mesh for planktonic foraminifera. Microfossils were picked using distilled water and counted:
120 planktonic/benthic foraminifers and benthic ostracods; benthics were taxonomically determined. A
121 subset of 114 cm samples has been used for this study, yielding more than 62 thousands of
122 specimens of foraminifers and ostracods. Microfossil databases contain 33,110 individuals
123 (planktonic foraminifers, PF), 27,616 individuals/181 species (benthic foraminifers, BF) and 1,299
124 individuals/70 species of ostracods. Taxonomic references used for foraminifers: Barker (1960),
125 Loeblich and Tappan (1988), Holbourn et al. (2013), web-updated in Hayward et al. (2016),
126 and for ostracods: Athersuch et al. (1989), Horne et al. (2002), Yasuhara et al. (2009).

127 The following quantification indices for microfossils have been used. Oceanity Index (OI;
128 PF/PF+BF; %), a paleobathymetric estimation (Murray, 1976). Diversity of benthic assemblages
129 has been measured with PAST 3 software (Hammer et al., 2001). Indices used for the studied
130 core samples are: number of species (S), Shannon (H), which varies from 0 in assemblages with
131 only one taxon, to higher values with many taxa; Equitability (J) measures the evenness of one
132 individual to belong to a particular species. Dominance D index, takes values from 0 (even
133 distribution in all species) to 1, when only one species dominates the assemblage, which indicates
134 ecosystem alteration. The increasing/decreasing observed trends of these indices provide us with
135 an estimation of stability/instability in the studied paleo-ecosystems.

137 **3. Results**

138 *3.1. Stratigraphy and age model of core PP10-17*

139 Stratigraphy of core PP10-17 is shown in Fig. 2. Lithologically it is composed of olive silty clay
140 sediment with bigger grains mostly during MIS 4 interval (see Granulometry, Fig. 2A). The 114
141 studied samples are grouped into main units (MIS 1 to MIS 5) with dates and shifts of
142 *Neogloboquadrina pachyderma* sin. (Nps) also indicated (Fig. 2B; data from Brocheray et al.,
143 2014). Nps are semi-quantitatively shown by the height of rectangles, the highest representing
144 above 95% relative of total planktonic foraminifera. Reference IMAGES core MD95-2042 from the
145 Tagus Abyssal Plain (Cayre et al., 1999a, b; Shackleton, 2001) is used as indirect estimation of
146 NE Atlantic Sea Surface thermal variation during the studied interval. We have drawn detailed
147 correlations with dated samples of core PP10-17, shown by arrows in Fig. 2C. In order to compare
148 these events with paleoclimatic signals, we use the standard core GICC05modelext-NGRIP 1,2,
149 (version 2014-12-10, 3-point average; Rasmussen et al., 2014; Seierstad et al., 2014) as a
150 reference for relative air temperature (T) and rapid climatic variations (Fig. 2D).

151 Age model for core PP10-17 is based on 38 dates (Table 1; Fig. 3A). Linear Least Squares
152 Regression of age-depth values shows a good correlation ($r= 0.96$; Fig. 3B), though the best fit is
153 performed with nonlinear logistic analysis (Fig. 3C).

154 3.2. Microfaunal analyses

155 The occurrence of Nps (*Neogloboquadrina pachyderma* sin.) in core PP10-17 (Fig. 2B) has been
156 used as chronostratigraphic reference. Thus, core samples with Nps have been depicted in the
157 following figures comparing with the occurrence of different assemblages of foraminifers and
158 ostracods, as showed below.

159 A relative sea-level “eustatic” signal is provided by the Oceanity Index OI (Fig. 4A). MIS 5 was an
160 oscillating interval (OI, mostly 60-90%) while the index increased and stabilized (OI, 90-100%)
161 during MIS 4 and MIS 3 intervals, with decreasing values at the beginning of H6 and H2. There is
162 an important and sustained decrease of the OI marking the LGM, and from H1 to recent the index
163 increased and kept very stable around 95%.

164 The occurrence of benthic foraminifer species oscillates around 27 spp./sample, with clear
165 decreases at the beginning of Heinrich events H4, 3, 2 and 1 (Fig. 4B). The presence of BF
166 species typical of shallower areas (coastal and estuarine) (Table 2A) marks intervals (end of H6 of
167 MIS 4, B/A of MIS 2) with important supply of detrital material to the deep studied area (Fig. 4C).
168 Main benthic foraminifer species occurrences in this core can be related to particular
169 environmental benthic conditions. For example, *Cibicides wuellerstorfi* is only present in noticeable
170 percentage in the core bottom samples (Fig. 5). Since this species is characteristic of cold
171 intervals with strong bottom circulation (see Table 3), it is possible that these samples belong to
172 the MIS 6a stadial (see Discussion chapter).

173 *Bulimina gibba* and *B. aculeata*, species indicative of hipoxia, were very important during
174 interstadials MIS 5a, c, e and interstadials of early MIS 3 (Fig. 5). On the other side, *Melonis*
175 *barleeanus*, a cold representative, was filling the gap between the latter, in the stadial 5d, while
176 *Melonis pompilioides* was also present in other stadials of MIS 3 and the YD (Fig. 5).
177 *Cassidulina laevigata*, a cold water, high-nutrient content and suboxic species (see Table 3), was
178 dominant during pre-H6 of MIS 4, the beginning of H2 and all the LGM (Fig. 6). *Globobulimina*
179 *affinis*, a cold, low ventilated, low oxygen and high content OM (organic matter) water species
180 (Table 3), dominated the benthic assemblages during Heinrich stadials (HS6, HS4, HS3, HS2,
181 HS1) and only in HS5 and LGM it was present with lower percentages (Fig. 6). *Uvigerina*
182 *peregrina*, a temperate-water species, is indicative of seasonal pulses of OM to the bottom (Table
183 3). This species is a good marker of the Holocene in this core (Fig. 6). The miliolid genus *Pyrgo*,
184 with the dominant species *P. murrhina*, is composed of a total of 6 species, characterizing cold
185 and oxygenated waters in this core, with shifts in C17, H5a, H4, H3, B/A and Holocene (Fig. 6).
186 Ostracods are regularly present in this core, but with low number of individuals and species, only
187 increased in the MIS 2 interval (Fig. 7). The analyses of ostracod species diversity (Shannon H
188 and Equitability J indices, Fig. 7), indicate relatively poor but stable environments for these
189 microcrustaceans. This is supported by the low values of H (mostly <1.4) with higher H (stable
190 environment) during MIS 5c, 5b, H3 and MIS 2. On the other side, index J is quite stable and high
191 (>0.7) during most of core intervals, with clear decreases (instability) during H5-H4 and the LGM-
192 H1 transition (Fig. 7).

193 *Krithe* and *Argilloecia* are dominant ostracods in the studied assemblages. Both genera are deep-
194 sea ostracods present in all oceans (Cronin et al., 2002). *Krithe*, usually the dominant genus, is a
195 cryophilic representative that has been successfully used as paleoceanographic indicator (Cronin
196 et al., 1999, 2000; Rodriguez-Lazaro and Cronin, 1999; Dwyer et al., 2000). The record of the
197 eight found species of *Krithe* exhibits a maximum value during the LGM with minor increases in
198 MIS 5b and the end of H1, H2 intervals (Fig. 8A). Considering the separate record of most
199 abundant species of *Krithe*, *K. trinidadensis* dominated during the LGM (Fig. 8B) and *K. aequabilis*
200 at the H1-B/A transition (Fig. 8C). *Argilloecia acuminata*, the dominant species of the genus, is
201 only present in MIS 5e, b, and LGM to the recent (Fig. 8D). Both *Krithe* and *Argilloecia* are shallow
202 infaunal genera (Majoran and Agrenius, 1995), and they were restricted in the studied sea-bottom,
203 due to the very reduced oxygen conditions. Only in intervals where dysoxic values decreased, as
204 MIS 5b, LGM and B/A, these ostracods were present, particularly during the LGM. The genus
205 *Krithe* is negatively affected by cold and strong dysoxic intervals and recovers during the
206 interstadials, with suboxic (*K. trinidadensis*) or oxic (*K. aequabilis*) conditions. Thus, these species
207 can be used as markers of benthic stressed conditions during Heinrich stadials with no deep-water
208 formation.

3.3. Sedimentologic indices

Magnetic susceptibility shows strong shifts at HS1c and H4, and minor picks at the end of H2, HS3 and H5 and the beginning of MIS 5b (Fig. 9). Heinrich event H6 is indicated by a minor increase of susceptibility values. These important shifts of magnetic susceptibility indicate a possible entrance of fine sediments from icebergs of northern precedence (Naughton et al., 2016), and will be used in discussion chapter to characterize events H4, H2 and H1.

Calcium is a major biogenic element in this core, where it was present in high percentages during interstadials MIS 5a, c, e, and Holocene, with other minor shifts at the end of H1, H2 and H4 (Fig. 10). Sr shows a similar trend as Ca. High values of Ca/Ti are related to higher productivity of calcareous plankton during warmer periods and lower siliciclastic input from the continent (Hodell et al., 2013). Ti/Ca is used as terrigenous sediment indicator (Bassetti et al., 2016). The low values of Ti in MIS 5 are characteristic of interglacials 5a, c, e in this core (Brocheray et al., 2014). Ti and Fe, as representative of the continent inputs, exhibit anti-covariant behavior relative to Ca and Sr, with higher values during stadials and decreasing from H1 towards the recent (Fig. 10).

4. Discussion

4. 1. Bottom conditions

Stability in the benthic paleoenvironment can be evaluated by means of diversity indices of benthic foraminifer and ostracod assemblages. In the case of foraminifers (Fig. 11), Shannon H and Equitability J indices show relative stability ($H > 2.0$, $J > 0.70$) during most part of core record, with minima/decreasing trend during stadials HS6, 5, 4, 3, 2, and particularly during the LGM, when a strong instability is deduced by the lowest values of Shannon and Equitability indices. The transition H2 to LGM (MIS 3 to MIS 2) marks the stronger alteration of benthos, with a progressive stabilization from the late H1 to the modern deep marine ecosystems in this area. Ostracod diversity and equitability (see Fig. 7 C, D) exhibit a more irregular pattern due to the scarcity of individuals, that prevents to the strict use of these indices, but show decreases (instability) during stadials MIS 5b, d, H6, 5, 4 and the end of LGM.

The oxygen content of benthic ecosystems is evaluated in this study by considering particular benthic foraminifer assemblages, indicative of oxic, suboxic and dysoxic environments (Table 2). The evolution of these assemblages in studied core (Fig. 11) shows very low (<10%) percentages of oxic species in most units of the core, with punctuated "oxic" intervals in MIS 5e, b, H5a, just before Heinrichs H4, H3, H2, and B/A and early Holocene (Fig. 11A). Most of the assemblages are suboxic or dysoxic. Suboxic species are clearly above 50% during MIS 5d-b, early MIS 4, MIS 3 interstadials and particularly, in the LGM (Fig. 11B). On the other hand, dysoxia was evident

243 during MIS 5e-d transition, 5c, a, C19, C17 and all the studied Heinrich events H1 to H6 (Fig.
244 11C).

245 Dysoxia and Equitability curves of benthic foraminifers are anti-covariant along most part of the
246 core record (see Fig. 11C, D). Since Equitability is an estimation of the stability of the benthos, this
247 anti-covariant trend evidences important bottom instability during a good part of MIS 5 to MIS 1
248 interval, very likely produced by the dysoxia that affected very negatively the epi- and hipo- benthic
249 ecosystems. Nevertheless the strongest alteration, indicated by minimum of Equitability (and
250 Shannon index) during LGM, was actually produced by important and persistent suboxia during
251 this interval (see Fig. 11B). These oxygenation minima are described as well during Heinrich
252 stadials HS1, 2, 3 and Younger Dryas (YD) in deep waters of SW Iberian Margin (Grunert et al.,
253 2015).

254 255 4.2. Paleoenvironmental characterization

256
257 Taking into account the results of different indicators used in this work, we synthesize the main
258 environmental features of the MIS 5 to MIS 1 interval (Fig. 12).

259 260 4.2.1. MIS 5

261 Two bottom samples in this core contain high percentage of *C. wuellerstorfi* (see Fig. 5), a cold
262 and high oxygen species living in waters with low organic flux from surface (see Table 3 for
263 ecological references in the discussion chapter). On the other hand, the element patterns during
264 this interval (Ca, Sr, minima; Ti, Fe, maxima; Fig. 10) is the same type of MIS 5d, b. These
265 findings let us think that this interval might belong to the end of stadial MIS 6a (Fig. 12), but the
266 lack of dates in these levels prevents to confirm this point.

267 MIS 5e is characterized by dominance of benthic foraminifer *Bulimina gibba* (Fig. 5), a warm
268 water, low ventilation, low O₂ and high OM content species (Table 3). BF infaunal dysoxic
269 assemblage increases in this interval (Fig. 11), and the ostracod diversity is stable (Figs. 7, 8),
270 indicating a relative stability of benthos. These signals could correspond with those indicated in
271 SW Iberian Margin by Grunert et al. (2015), that the inception of interglacial MIS 5e produced
272 reduced trophic conditions and ventilation by NEADW (North East Atlantic Deep Water) increased.
273 During MIS 5d *Melonis barleeanus* and *M. pompilioides* entered in this record. Both are cold,
274 suboxic water species, with input of OM (Table 3). BF assemblages are suboxic-oxic (Fig. 11) and
275 the species number S increased during this interval (Fig. 4). Ostracods on the contrary, suffered a
276 fall of diversity at the beginning, due to the suboxia, and then they were present in low numbers,
277 also during all the 5c (Figs. 7, 8). This unit registered the first sea surface cooling in this core,

278 though it was not very important, since there was a little signal of Nps (Fig. 2B). This cooling
279 corresponds with the end of GS26 of GICC05modelext (Fig. 2D).
280 During MIS 5c there were conditions very similar to that of described to 5e (see Fig. 12).
281 MIS 5b exhibits similar characteristics of 5d, but with the entrance of new species as *Cassidulina*
282 *laevigata*, which confirms the seasonal OM pulses indicated for 5d (Table 3). The increase of
283 ostracod *Krithe* in these levels supports some renovation of deep waters. In this unit it is registered
284 the second cooling (but stronger than the first one, see Nps signal in Fig. 2B).
285 Finally, MIS 5a contains similar BF and elements described for previous interstadials 5e, c. As we
286 will see later, *Krithe* is negatively affected by the reduction of deep-water formation produced
287 during the stadials. The decrease of *Krithe* in these levels of 5a occurs just before the entrance of
288 three short cooling intervals (see Fig. 8A) and might indicate a certain restriction in benthos during
289 this time. The three intervals of cold SST are marked by Nps shifts (the second one, at 73.9 ka,
290 corresponds to GS20 of GICC05modelext, Fig. 2D, and C20 of Fig. 2C).

291

292 4.2.2. MIS 4

293 The first signal is the strong shift of *C. laevigata* (Fig. 6), opportunistic species associated with
294 seasonal fluxes of OM. This species is characteristic of glacial stages MIS 4 and MIS 2 in the
295 Mediterranean (Singh et al., 2015; Table 3). A comparable shift of *C. laevigata* at the beginning of
296 H6 has been signaled in the Alboran Sea (W Mediterranean) coincident with a strong fall of $\delta^{13}\text{C}$
297 (Perez Martin et al., 2006). In the Portuguese margin this species occurred during glacial stages
298 with shifts synchronic with paleoproductivity (Baas et al., 1998).

299 Heinrich H6 signal started with strong decrease of OI (Fig. 4) and increasing of BF dysoxics (*B.*
300 *gibba* among others, see Table 3). After this, OI increased (and stabilized from the beginning of
301 H6 onwards) and a different BF assemblage contains *G. affinis*, with increasing values during H6
302 (see Fig. 6). *G. affinis* is a deep bathyal species, living in high productivity, high OM waters and
303 tolerating total dysoxia conditions (Table 3). At the same time, *Krithe* reduced drastically during
304 these levels (Fig. 7). These findings point to reduced deep-water formation produced by AMOC
305 weakening or even shutdown.

306 At the end of H6 there was the stronger shift (37% of coastal BF species; see Fig. 4, Table 2) of
307 detrital input in these waters. Heinrich stadial H6 was an interval with deep, cold and low ventilated
308 waters, very low oxygen content and high percentage of OM. The mentioned detrital input at the
309 end of H6 is coincident with the HS6 (61.9 ka BP; see Fig. 4), that is, the coldest interval of this
310 event, suggesting that they are produced during low eustatic levels, responsible of increasing
311 erosion and transportation to the deep benthos.

312 The end of MIS 4 is coincident with a decrease of *G. affinis* and the entrance of *P. murrhina* (Fig.
313 6). The later species lives in very cold and oxic waters (Table 3) and indicates the beginning of the
314 bottom currents reactivation in this area.

315

316 4.2.3. MIS 3

317 This unit started with cold, low ventilation, low oxygen and high OM waters (*G. affinis*). The
318 entrance of *M. pompilioides* suggests colder bottom waters and flux of OM from surface
319 productivity (Fig. 5, Fig. 6, Table 3). The occurrence of elevated percentages of *P. murrhina* (in
320 sample 1101 cm) marks the effect of well-oxygenated waters at this point (see also Fig. 11), likely
321 due to a relative reactivation of bottom current, defining the stadial H5a (Fig. 6), but it was not
322 important enough to produce the recovering of benthic ostracod *Krithe* (Fig. 8).

323 This bottom reactivation is rapidly inactivated (*B. gibba*, warmer, dysoxic waters) during the GI
324 (Greenland Interstadials) 13, 12, 11 (Fig. 5). The occurrence of *M. pompilioides* in GI 13, attests
325 the effect of OM fluxes from the surface. During H5 and specially H4, *G. affinis* marks a new
326 cooling with dysoxic waters and high OM content (Fig. 6, Fig. 11, Fig. 12). From H4 to H3 we
327 found important variations of these indicators. The stronger shift of magnetic susceptibility is found
328 at the end of H4 (Fig. 9), which suggests that at least fine sediments from icebergs of Northern
329 Atlantic origin reached this location (Naughton et al., 2016). Suboxic-oxic waters dominated during
330 this interval, except two moments with marked dysoxia (*G. affinis*; Fig. 6, Fig. 11). Shifts of *G.*
331 *affinis* are described in the H4 of Portugal (Baas et al., 1998) and the H4 with IRD maxima in Bay
332 of Biscay (Loncaric et al., 1998).

333 After the H4 cold and well-oxygenated waters (*C. wuellerstorfi*) alternated with low oxygen (*M.*
334 *pompilioides*) and warmer and high seasonal productivity waters (*U. peregrina*, Fig. 6). This
335 interval ended just before H3 with the entrance of well-oxygenated waters (*P. murrhina*) indicative
336 of bottom current reactivation. This oxygenation was favorable for the ostracods that responded
337 increasing their diversity (Shannon H, Fig. 7C).

338 The indicators of H3 are the same as for H5 and H4 relative to *G. affinis*, suggesting a low-
339 ventilated bottom, though the absence of *Bulimina* could indicate a not so restrictive condition. The
340 increase of diversity of *Krithe* during H3 supports this point.

341 After H4 and up to end of H3 there was an increase of coastal species in the assemblages,
342 indicative of some climatic reactivation. Cold and dysoxic waters (*G. affinis*) persisted up to the
343 end of MIS 3, and only in two intervals where this species decreased, *C. laevigata* was indicative
344 of well-oxygenated and intermittent flux of OM waters, as is evident in the early H2 (Fig. 6).

345

346 4.2.4. MIS 2

347 LGM is characterized by a strong decrease of relative sea level (OI around 70%, Fig. 4). Waters

348 were very strong suboxic and with high nutrient content (*C. laevigata*, Fig. 6), conditions that
349 affected negatively the BF assemblages (equitability and diversity very low (Fig. 11), but not for
350 the case of the ostracods, that increased their presence in these levels (Fig. 7). *C. laevigata* has
351 been described as a common species in the Mediterranean MIS 2 (Singh et al., 2015).
352 At the beginning of H1 the bottom was very unfavorable for the benthics (71% of *G. affinis*, lowest
353 number of BF species, S = 8 spp., Fig. 4); low individual numbers, species and equitability for the
354 ostracods, Fig. 7). During H1 the oxygen recovered to oxic-suboxic conditions, the OI increased
355 and stabilised and at the same time the percentage of *G. affinis* decreased up to 24% during this
356 event (Fig. 6). These conditions favored the recovery of BF (Fig. 11D, E) and ostracods (Fig. 7). A
357 comparable H1 with a shift of *G. affinis* was described in other locations of the Bay of Biscay by
358 Loncaric et al. (1998).
359 The B/A (Bolling/Allerod) interval was characterized by well-oxygenated waters (*P. murrhina*,
360 *Krithe aequabilis*, *A. acuminata* and by the arrival of shallow allochthonous specimens (Fig. 4, Fig.
361 6, Fig. 8). The YD was under the influence of cold, suboxic and nutrient-rich waters (*M.*
362 *pompilioides*) (Fig. 5, Fig. 11).
363 HS1 was the most extreme of cold intervals, providing further evidence for a severe temporary
364 reduction or even shutdown of AMOC in the North Atlantic and its export to the SW Iberian Margin
365 (Grunert et al., 2015). Naughton et al., (2016) described Heinrich stadial 1 (HS1; 18.5-14.5 ka) as
366 a complex interval with three phases: HS1a, (18.5-17.75 ka) extremely cold and relatively wet, SS
367 cooling (10-8°C), shift of NPs, shift of magnetic susceptibility; HS1b, (17.75-16.1 ka), cool and dry,
368 NAO+(?), and HS1c, (16.1-14.6 ka) of relative sea-surface warming (2°C), increasing of moisture
369 and IRD shift.
370 We located the HS1c in core PP10-17 at the very end of H1, in sample 101 cm (16.1 ka BP, Table
371 1, Fig. 9), coincident with the important shift of magnetic susceptibility. We also located HS1a in
372 sample 171 cm (18.5 ka BP, Table 1, Fig. 9), coincident with a minor shift of Nps.
373 Supporting these findings, SSTs of core MD95-2042 are seasonally depicted by Cayre et al.
374 (1999a), showing important cooling (up to -12°C) during HE1 in SW Iberian margin. The shift of
375 transported coastal species observed in the early B/A (Fig. 4C) could have been produced by a
376 melting pulse typical of deglaciation interval.

377

378 4.2.5. MIS 1

379 This interval has been relatively poorly studied, with only 5 samples. It is characterized by the
380 occurrence of *Uvigerina peregrina* (Fig. 6), a typical species of the Holocene, indicative of well-
381 oxygenated waters, with seasonally pulsed organic matter fluxes to the seafloor (Garcia et al.,
382 2013) and high productivity (Table 3). The presence in these levels of *P. murrhina* confirms the
383 mentioned quality of waters. With the inception of MIS 1, OM supply reduced and a better-

384 ventilated deep-water environment bathed by NEADW, was established in SW Iberian Margin
385 (Grunert et al., 2015).

387 **5. Conclusions**

388 Deep-sea benthic responses to rapid paleoclimatic and paleoceanographic changes of the SE Bay
389 of Biscay are characterized for the MIS 5 to MIS 1 interval.

390 Benthic foraminifer assemblages characterize the succession of oxic, suboxic and dysoxic
391 environments, related to stadial/interstadial inceptions.

392 Clue-species of benthic foraminifers and ostracod assemblages evidence particular conditions of
393 the benthos, relative to temperature, oxygen, OM and productivity of this interval. The stadials (low
394 Ca content during MIS 5) are evidenced by variable dysoxia, which is better supported by BF
395 species adapted to dysoxic waters, but produced stress conditions for the ostracods. These cold
396 phases are marked by the occurrence of BF deep infaunal species *Globobulimina affinis* (Heinrich
397 stadials, cold and very low oxygen and high OM), and by shallow infaunal species *Melonis*
398 *barleeanus*, *M. pompilioides*, *Pyrgo* spp. and *Cibicides wuellerstorfi* (other stadials, with higher
399 oxygen content).

400 Interstadials are characterized by high Ca content (MIS 5), temperate and dysoxic waters with
401 deep infaunal species (*Bulimina gibba*, strong eutrophic and anoxic benthos) during interstadials
402 of MIS 5 to mid MIS 3 (GI 25 to GI 10) and by shallow infaunal (*Cassidulina laevigata*, seasonal
403 OM fluxes to the bottom) in other interstadials from GI 9 to LGM. The ostracods, particularly *Krithe*
404 spp., increased during interstadials, evidencing some deep-water formation.

405 LGM is characterized by strong suboxic waters with *Cassidulina laevigata*. MIS 1 is characterized
406 by the occurrence of temperate species *Uvigerina peregrina*.

407 AMOC reduction is evidenced during cold stadials, (or shutdown, at least during H6, and maybe
408 H1) by the indicated response of benthic foraminifer and ostracod species.

738 **Figure 1.** Location of studied area with core PP10-17 and core MD95-2042.

739 **Figure 2.** Stratigraphy of core PP10-17, compared with standard marine MD95-2042 and ice
740 GICC05modelext-NGRIP cores. A-B, data from core PP10-17. A. Granulometry indicating silty
741 clay size sediment with bigger grains mostly during MIS 4 interval. B. Samples studied in core
742 PP10-17, grouped into main units. Tie-points of Heinrich stadials (HS) and Greenland
743 interstadials (GI) with dates from **Table 1**. Shaded (blue in web version) rectangles are shifts of the
744 cold-water planktonic foraminifer *Neogloboquadrina pachyderma* sin. (Nps), the height of
745 rectangle is the approximate percentage of Nps (highest is >90%), indicative of the sea- surface
746 cold intensity. Dates (see **Table 1**) and events are indicated. H1 to H6, Heinrich events. GI, 1 to 25,
747 from core GICC05modelext-NGRIP. C. Reference core MD95-2042 (Cayre et al., 1999a;
748 Shackleton, 2001) is used as comparative model for SST during the studied interval. Detailed
749 correlations with dated samples from core PP10-17 are shown by arrows. D. Core
750 GICC05modelext-NGRIP 1,2, version 2014-12-10, 3-point average (Rasmussen et al., 2014;
751 Seierstad et al., 2014) used as reference for air T and rapid climatic variations. GS, Greenland
752 Stadials (1 to 26). NPs occurrences modified from Brocheray et al., 2014. Age of events after
753 Gottschalk et al., 2015. C17 to C20 are cold intervals for MIS4-MIS 5a (Sanchez-Goñi et al.,
754 2013).

755 **Figure 3.** Age model for core PP10-17 based on 38 dates (Tab. 1). A. Correlation age-depth.
756 Horizontal scale with studied samples (cm; for clarity, only one of two samples have been
757 displayed), grouped into stratigraphic units. Position of main events is indicated. Vertical shaded
758 columns are Heinrich stadials after (Nps) maxima as indicated in Fig. 2. Dates are AMS ¹⁴C
759 datations (wide rectangles), tie-points with core MD95-2002 (black rectangles), with NGRIP
760 (triangles) and Martinson et al. (1987; diamonds) (after Brocheray et al., 2014). Tie-points in
761 vertical scale are taken from Otvos (2014), Gottschalk et al. (2015) and Naughton et al. (2016). B.
762 Linear Least Squares Regression of age-depth values of core PP10-17 shows a good correlation
763 ($r = 0.96$), though the best fit is performed with nonlinear logistic analysis (Fig. 3C). Software used
764 is PAST 3 (Hammer et al., 2001).

765 **Figure 4.** Foraminifers in core PP10-17. A. Oceanity Index (OI, n° planktonic forams/total forams
766 %) an estimation of the relative eustatic level. B. Benthic foraminifer species (with error bars)
767 present in these samples, indicative of richness in benthic ecosystems. C. Benthic foraminifer
768 coastal species (see Table 2), with marked shifts at the end of MIS6 and Bølling-Allerød, produced
769 by inputs from shallower waters. In bottom of figure, core samples with dates, Greenland
770 interstadials (GI) and shifts of Nps (representing cold intervals, see Fig. 2) are indicated for
771 comparison.

772 **Figure 5.** Occurrence in core PP10-17 of major benthic foraminifer species *Cibicides wuellerstorfi*,
773 *Bulimina gibba + aculeata*, *Melonis barleeanus* and *Melonis pompilioides*. Bottom of figure as
774 indicated in Fig. 4.

775 **Figure 6.** Occurrence in core PP10-17 of major benthic foraminifer species *Cassidulina laevigata*,
776 *Globobulimina affinis*, *Uvigerina peregrina* and *Pyrgo murrhina + spp.* Bottom of figure as
777 indicated in Fig. 4.

778 **Figure 7.** Ostracods in core PP10-17. A. Number of individuals. B. Number of species. C.
779 Shannon H index of species diversity: increasing trends indicate stabilization of benthic
780 ecosystems. D. Equitability J index: values close to one indicate stable environment. Bottom of
781 figure as indicated in Fig. 4. Databases for these indices in Appendix A.

782 **Figure 8.** Occurrence of major benthic ostracod species in core PP10-17. A. Record of the eight
783 species of *Krithe* found in this core. B. *Krithe trinidadensis*. C. *Krithe aequabilis*. D. *Argilloecia*
784 *acuminata*. Bottom of figure as indicated in Fig. 4.

785 **Figure 9.** Magnetic susceptibility SI in core PP10-17. Major shifts are located at the end of
786 Heinrich events H1 to H5. Bottom of figure as indicated in Fig. 4.

787 **Figure 10.** Element content (3-point average) of Ca, Sr, Ti and Fe in core PP10-17. Bottom of
788 figure as indicated in Fig. 4.

789 **Figure 11.** Benthic foraminifer (BF) oxygen-content assemblages and diversity in core PP10-17
790 (see also Table 2). A. Oxic assemblage. B. Suboxic assemblage. C. Disoxic assemblage. D. BF
791 Equitability J index. E. BF Shannon H species diversity index. Bottom of figure as indicated in Fig.
792 4. Databases for these indices in Appendix A.

793 **Figure 12.** Synthetic data of the proxies used in this work, including characteristic assemblages
794 and diversities of planktonics foraminifers, benthic forams and ostracods, susceptibility and
795 element content. Blue rectangles are Nps shifts in core PP10-17, indicative of cold SST in Central
796 West Atlantic.

797 Oxygen content: O, oxic; S, suboxic; D, dysoxic. Benthic signal: +, increase; -, decrease.

798 Productivity: OM, high organic matter; UP, upwelling; MES, mesotrophic. Benthic microhabitat: DI,
799 deep infaunal; II, intermediate infaunal; SI, shallow infaunal.

		<i>Valvulineria bradyana</i> (Fornasini, 1900)	

Table 2. Benthic foraminifer assemblages used in this work. A. Benthic foraminifer coastal species present in core PP10-17, used in Fig. 4C. The list includes species living in coastal and estuarine settlements of Bay of Biscay (Pascual et al., 2008; Martínez-García et al., 2013). B. Benthic foraminifer assemblages indicative of oxygen content (after Kahio, 1994, 1999).

Species	Dissolved-oxygen	Microhabitat	Ecological preference
<i>Cibicides wuellerstorfi</i> (Schwager, 1866)	Oxic (> 2ml/l)	Shallow infaunal (Fontanier et al, 2003)	Cold (-2 to 4°C) and deep water (1360-4280 m) (Murray, 1991), high oxygen content (>2ml/l) (Kahio, 1994, Schmiel et al., 1997). OM flux relatively low (Gooday, 2003) locally adapted to pulses of organic carbon (De and Gupta 2010; Diz and Barker, 2016). Increasing of its occurrence in the paleo-assemblages is indicative of increasing of deep bottom waters (Bornmalm et al., 1999). This species is associated with NADW (North Atlantic Deep Water) and ACW (Antarctic Circumpolar Water) (Douglas and Woodruff, 1981; Murray, 1991).
<i>Bulimina gibba</i> Fornasini, 1902	Disoxic (0.1-0.3 ml/l)	Deep infaunal (Mendes et al., 2004)	In this core, two main species of <i>Bulimina</i> (<i>B. gibba</i> , <i>B. aculeata</i>) are cool-temperate (5-17°C) (Murray, 1991) and high productivity waters (Ray and Singh, 2012). In particular, <i>B. gibba</i> is typical of strongly eutrophic and anoxic environments (Fontanier et al., 2002).
<i>Bulimina aculeata</i> d'Orbigny, 1826	Suboxic (0.3-1.5ml/l)	Deep infaunal (Fontanier et. al, 2002; Rai and Singh, 2012)	<i>Bulimina aculeata</i> is associated to elevated fluxes of organic carbon in bathyal waters (Mackensen et al., 1990; Wells et al., 1994).
<i>Melonis barleeanus</i> (Williamson, 1858)	Suboxic	Shallow infaunal /Intermediate infaunal (Fontanier et al., 2003; Grunert et al, 2015)	<i>Melonis barleeanus</i> is a cold water species (-0.4 to 9°C), with depth range 280 to 2710 m (Murray, 1991). It tolerates high concentrations of OM (Fontanier et al., 2002). It is present in virtual absence of oxygen and low nitrates (Jorissen et al., 1998). Indicative of deep mesotrophic conditions (Jorissen, 2003; Grunert et al., 2015).
<i>Melonis pompilioides</i> (Fichtel and Moll, 1798)	Suboxic	Shallow infaunal (Mojtahid et al., 2010). Intermediate infaunal (Grunert et al., 2015)	<i>Melonis pompilioides</i> is a cold water species (4.9°C) (Frerichs, 1970), oportunistic adapted to high concentration of food and tolerates high organic detritus fluxes (Baas et al., 1998), typically occurring during cold intervals in cores (Corliss, 1983). Shifts of this species are related with the entrance of OM (Grunert et al., 2015).
<i>Cassidulina laevigata</i> d'Orbigny, 1826	Suboxic	Shallow infaunal (Fontanier et al, 2002)	<i>C. laevigata</i> has been related with upwelling (Levy et al., 1995). It is an oportunistic species adapted to high food content (Baas et al., 1998), with high organic carbon flux (>3 gC/m/yr) (Jorissen et al., 2007). It is also present in areas of seasonal flux of OM (Rasmussen et al., 2002). In Portugal it is present in glacial periods, with shifts of paleoproductivity (Baas et al., 1998). This species (as <i>C. carinata</i>) was abundant during MIS 2 and MIS 4 in the Mediterranean (Singh et al., 2015).
<i>Globobulimina affinis</i> (d'Orbigny, 1839)	Disoxic	Deep infaunal (Fontanier et al, 2003; Geslin et al., 2004)	<i>Globobulimina</i> is a cold water genus. <i>Gl. affinis</i> is a bathyal species living in sediments with high OM content (Fontanier et al., 2005). It is cosmopolitan in areas of high productivity, high carbon content and disoxic waters (Hayek and Wilson, 2013; Patarroyo and Martinez, 2016), but prefers anoxic conditions (Geslin et al., 2004; Fontanier et al., 2002), by active migration inside the sediment to find this anoxic preferred habitat (Geslin et al., 2004). This low-oxygen adaptation makes this species a good proxy for strongly disoxic environments (Schonfeld, 2001; Jorissen et al., 2007; Grunert et al., 2015). It is present in HE4 in Portugal (Bas et al., 1998), and HE1, HE4 with IRD shift in the Bay of Biscay (Loncaric et al., 1998).
<i>Uvigerina peregrina</i> Cushman, 1923	Suboxic	Shallow infaunal/ Intermediate infaunal (Fontanier et al., 2002, 2003)	<i>Uvigerina peregrina</i> is a temperate (6-15°C) species (Murray, 1991), indicative of high productivity waters (Lutze, 1986; Ray and Singh, 2012; Patarroyo and Martinez, 2016), and positively correlated with OM in the sediment (Fontanier et al., 2002). This is a dominant species when organic carbon flux exceeded 2-3 g/m ² a (Altenbach, 1988). Tolerates virtual absence of oxygen (Lohmann, 1978), becoming dominant in upwelling areas (Debenay and Konate, 1987). Thus, the abundance of <i>Uvigerina peregrina</i> suggests seasonal phytodetritus fluxes exported from surface with strong seasonal productivity (García et al., 2013). <i>U. peregrina</i> is one of the species that better tolerates the low quality of OM, characterising mesotrophic and oligotrophic environments (Mojtahid et al., 2010). It is influenced by the upper NADW or CDW (Circumpolar Deep Water) (Schnitker, 1979).
<i>Pyrgo murrhina</i> (Schwager, 1866)	Oxic	Shallow infaunal (Kuhnt et al., 2007)	<i>Pyrgo murrhina</i> is a cold water (<3°C) species (Murgese and De Deckker, 2005), living in bathyal Atlantic (Gudmundsson, 1998), in areas with low organic carbon flux and high oxygen content (>3.5 ml/l) (Altenbach et al., 1999; Murgese and De Deckker, 2005). It has been related with periods of increasing deep water formation with nutrient increase (Bornmalm et al., 1999). It is living in oligotrophic environments (García et al., 2013). Present in glacial stages of Portugal (Baas et al., 1998). This species is a good proxy of oxygen waters (Caulle et al., 2014), being almost absent when the waters become disoxic.

Table 3. Ecological preferences of the most characteristic benthic foraminifer species in core PP10-17. Dissolved oxygen levels after Kahio (1994, 1999).

-Deep-sea benthic response to rapid paleoclimatic changes (MIS 5 to MIS1) is analyzed.

-Stadials and interstadials are evidenced by shallow/deep benthic microhabitats.

-Intervals with deep-water formation are evidenced by particular benthic assemblages.

-Oxygen content is a main factor controlling deep-sea bottom ecosystems.
